THE TREATMENT OF ECLAMPSIA

CHAIRMAN'S ADDRESS

PIERCE RUCKER, M D
RICHMOND, VA

Eclampsia is still a major problem in obstetrics. In the time at my disposal I propose to discuss its treatment. I shall limit myself to cases of actual puerperal convulsions. Not that eclampsia without convulsions or preeclampsia is not as important or as dangerous. In the first place the convulsive type is more clear cut and there is scarcely any question of diagnosis. In the second place the therapeutic problem is different. When convulsions are present, one naturally has an urge to energetic treatment which is egged on by the patient's relatives and friends. One simply has got to do something. In preeclampsia, on the other hand, it is frequently hard to make the patient realize that she is seriously ill, and one has to overcome her resistance to treatment of any sort.

Treatment naturally divides itself into two parts (1) preventive and (2) curative. In no disease is the old adage that "an ounce of prevention is worth a pound of cure" more true than with eclampsia. With good antepartum care one can in the vast majority of cases recognize the premonitory signs and symptoms in time to avoid convulsive seizures. A rise in blood pressure or an unusual gain in weight is a warning that treatment should begin. If the patient does not improve with rest in bed, a milk diet and possibly the exhibition of calcium by mouth or intravenously, or, if albuminuria appears, the uterus should be emptied. A patient who carries a hypertension for three weeks is apt to have permanent damage.

Whereas there is a general unanimity of opinion with regard to the preventive treatment, when one comes to curative treatment of eclampsia that is another matter. I was taught that, as the cause of eclampsia was in some way connected with the presence of the fetus, the proper treatment was to terminate the pregnancy as quickly as possible. By getting rid of the cause, one cured the disease. The standard method was accouchement force, which was later supplanted by cesarean section. This method was so standardized that I followed it blindly for years. When I counted up my results I was surprised to find that I had lost 31.6 per cent of the mothers. I then went through the era of morphine, colonic irrigation and gastric lavage, with a maternal mortality of 25.9 per cent. The first effective means of controlling convulsions was magnesium sulfate given intravenously. Its use tremendously simplified the treatment of this condition. Since the appearance of Lazard's article in 1925, I have

treated 129 consecutive cases of eclampsia with a maternal mortality of 4.65 per cent. It is to the treatment of these 129 cases that I want particularly to direct attention.

Of the 129 patients, seventy were white and fifty-nine were colored. The ages varied from 12 years to 40 years, the average being 23.7 years. Eight white patients were unmarried and twenty-five of the Negroes were unmarried. There were fifty white primiparas and forty-four colored primiparas, a total of ninety-four primiparas, or 73 per cent.

No attempt was made to classify the convulsions into antepartum, intrapartum or postpartum for the reason that in many cases no adequate history could be obtained. Many patients were brought into the hospital in coma or convulsions by the ambulance and no one seemed to know much about the case. For the same reason I have not been able to classify all the cases according to their severity. The total number of convulsions in many cases is unknown. At least forty-one cases were severe according to Eden's classification. There were six maternal deaths, five of which occurred in the severe type. These deaths were discussed in a previous paper.¹ Briefly, two cases, 10 and 15 of my series, were treated with morphine and high colonic irrigations. One mother died of pneumonia on the fourteenth day after a spontaneous delivery. She had antepartum convulsions, which were easily controlled with magnesium sulfate intravenously. The fourth case was also a septic death. The patient was delivered by cesarean section after a trial labor of fifty-two hours, several days after the convulsions were stopped. She died of peritonitis on the third day. The fifth maternal death was that of an epileptic with superimposed puerperal convulsions. I was unable to control the convulsions, and the patient died undelivered ten hours after admission to the hospital. The last maternal death was of a patient who was admitted to the hospital in May 1929. She had had twelve convulsions before she was put to bed in the hospital. Magnesium sulfate intravenously failed to stop the convulsions. The spinal fluid was cloudy and under a pressure of 240 mm of water. I delivered her of a stillborn baby by version under spinal anesthesia. The patient continued to have convulsions and died two and a half hours after delivery. Three mothers had twins. Stroganoff² in a recent paper reported a high maternal mortality in twin cases treated with magnesium sulfate. This is contrary to my experience. All three mothers, as well as the six babies, recovered. In eleven cases of mothers brought into the hospital after the baby was born, there is no record of the baby. Sixty-five babies left the hospital alive and fifty-six babies were lost, a fetal mortality of 46.6 per cent.

Read before the Section on Obstetrics Gynecology and Abdominal Surgery at the Eighty Eighth Annual Session of the American Medical Association Atlantic City N J June 10 1937

1 Rucker M P Virginia M Monthly 61 384 (Oct.) 1934
2 Stroganoff W and Davidovitch O J Obst & Gynec Brit Emp 44 289 (April) 1937

In the group of severe eclampsia there was one set of twins and two babies whose outcome was not recorded. Twenty-four babies in this group were lost and sixteen left the hospital alive, a fetal mortality of 60 per cent. Even more striking is the fetal loss in the cases in which the maternal systolic blood pressure went over 200 mm of mercury, whether they had any of the other stigmas of severe eclampsia or not. There were twenty-three such cases with fifteen fetal deaths, six live babies and two unrecorded, a fetal mortality of over 71 per cent.

TREATMENT

In the treatment of these cases, I have not followed slavishly a routine but have been guided by certain principles. Mine consist of four: (1) stopping the convulsions, (2) good nursing care with emphasis on rest, (3) promoting kidney activity, and (4) digitalis.

Magnesium sulfate intravenously has been remarkably efficient in stopping convulsions. My initial dose is 20 cc of a 10 per cent solution. Frequently I have given a second dose of 15 cc and occasionally a third dose of 15 cc. In a few cases I have used $7\frac{1}{2}$ grains (0.5 Gm) of sodium amytal intravenously. I prefer the magnesium sulfate to the sodium amytal, because the former wakes the patient up when it stops the convulsions and the latter puts her to sleep. In such an event it is hard then to know whether the patient is comatose or simply drugged. Nevertheless, sodium amytal is a drug to have around, because occasionally one drug will control the convulsions when the other will not.

Under the head of good nursing care comes the avoidance of external stimuli, such as bright light, noises and jarring the bed. The patient should be kept on her side to lessen the chance of aspirating vomitus and other fluids in the mouth. The tongue should be protected during the clonic stage of a convulsion, and the nurse should be prepared to give artificial respiration if it should be necessary. Too much emphasis cannot be placed on rest. For this reason I am opposed to colonic irrigations, gastric lavage and purgatives. These patients are desperately ill and need all the rest they can get.

I feel very much better when the patient is putting out a good quantity of urine. Usually I rely on water or cream of tartar lemonade to promote kidney activity. The best way to give fluids to an eclamptic patient is by the stomach. If the patient is not awake enough to drink, one can slip a nasal tube into the stomach and pour in a pint of fluid every eight hours. When there is anuria or marked oliguria I resort to dextrose intravenously, varying the strength according to whether there is much or little edema present.

Digitalis has a definite place in the treatment of eclampsia. I give half a cat unit dose as soon as possible after I have given the magnesium sulfate or sodium amytal. I have never seen edema of the lungs when digitalis has been given. In this connection the recent report of Ware and Noblin³ is especially interesting, as a large part of my series is composed of patients treated at St. Philip's and Memorial Hospital immediately prior to the time covered in their report. In 1931 and 1932 when they used morphine, bromide and chloral their mortality was 25.53 per cent. In 1933, 1934 and 1935 they used magnesium sulfate, dextrose and digitalis and their mortality dropped to 6.88 per cent. Dr. Ware tells me that in 1935 and 1936 he

treated thirty-seven eclamptic patients with only one maternal death. In other words, at the Medical College of Virginia Hospitals I was treating eclampsia with magnesium sulfate, rest and digitalis, with a maternal mortality of 5 per cent. The treatment was then changed to morphine, bromides and chloral and colonic irrigations and the mortality rose to 25 per cent. The treatment was then changed back to practically the same as before and the mortality dropped to practically the same figure.

I have said nothing about delivery or terminating pregnancy, for the reason that I believe it has no place in the treatment of eclampsia. The patients who go into labor should be treated as conservatively as possible, which means in most cases episiotomy and low forceps under local anesthesia. When antepartum eclampsia is relieved and the patient is putting out a good quantity of urine, then comes up the question of terminating pregnancy. Unless one has exceptionally good control of the patient, it is unwise to let the patient leave the hospital undelivered. No eclamptic or recent eclamptic patient should have a general anesthetic.

SUMMARY

A series of 129 consecutive cases of eclampsia have been treated with an uncorrected maternal mortality of 4.65 per cent. The guiding principles in the treatment of these patients have been (1) stopping the convulsions with intravenous magnesium sulfate or sodium amytal, (2) the greatest possible amount of rest, (3) promoting kidney activity with fluids by mouth or dextrose solution intravenously, and (4) adequate dosage of digitalis.

ACTIVE IMMUNIZATION OF TUBERCULOUS CHILDREN AGAINST WHOOPING COUGH WITH SAUER'S VACCINE

MORRIS SIEGEL, M.D.

AND

ESTHER W. GOLDBERGER, M.D.

NEW YORK

Shortly after Sauer's early reports of his success in the prevention of whooping cough with doses of 80 billion bacilli of an unwashed vaccine prepared from freshly isolated strains of *Haemophilus pertussis*, it was decided to test the effectiveness of the vaccine at Sea View Hospital under adequate control conditions.

At Sea View Hospital tuberculous persons of all ages are admitted from hospitals and homes of New York City and hospitalized for the duration of their illness. In the pediatrics service there are almost 200 patients under 16 years of age with tuberculosis or suspected of having tuberculosis. The average duration of hospitalization for the tuberculous children is about two years. Newly admitted children are kept in the pediatrics admitting ward for several weeks and are then transferred to one of the other wards. For those over 6 years of age there is a separate ward for boys and girls. They intermingle in the hospital school. For the children under 6 years of age there is one ward for infants, boys under 3 years and girls under 6 years of age, and another ward for boys between the ages of 3 and 6 years. These younger children remain in their respective wards throughout the day. They are in

From the Pediatrics Service of Dr. Bela Schick, Sea View Hospital, Staten Island.

intimate contact with one another but do not mingle with children in other wards. Those with positive sputum are separated from the others in each ward. In addition there is a ward for those with bone tuberculosis and a small ward for normal infants vaccinated with BCG. Visitors are allowed daily between 3 and 5 p. m. Children are not permitted to visit the wards.

Since several cases of whooping cough occurred among our younger children in 1931 and in 1934, we felt that there might be another outbreak in two or three years. This would give us the opportunity to test the effectiveness of Sauer's vaccine under known conditions of prolonged and intimate exposure during the catarrhal stages of the disease before the diagnosis is made and when the disease is most contagious, and to compare the outcome among vaccinated and non-vaccinated children living under similar conditions of exposure.

Unfortunately it is difficult to obtain comparable conditions in respect to exposure among vaccinated and control children in studies among children in the general population. In such studies it is particularly difficult to evaluate the degree of exposure among children under investigation unless familial exposure occurs. When there is no familial exposure, it is possible to follow up large groups of children for long periods of time without finding a single undoubted exposure. In cases in which extrafamilial exposure is reported, it is often difficult to determine the degree of the exposure or to be certain that the disease was in its communicable phase when contact took place, even though whooping occurred at the time. It is common knowledge that the infectivity of whooping cough diminishes with the duration of the disease and that a paroxysmal cough can be observed long after the disease has ceased to be infectious. Because of this, reports of extrafamilial exposure not only lose much of their significance as tests of the effectiveness of the vaccine but also can be highly misleading.

Since the degree of exposure varies considerably among the children in a study, and since many children never develop recognizable symptoms of whooping cough, it is obviously essential to choose systematically during the periods of vaccination an adequate number of unvaccinated children as controls if the truth is to be learned about the value of vaccines in whooping cough prophylaxis. This need for adequate controls in the study of whooping cough prophylaxis is well illustrated by the reports of from fifteen to twenty years ago. At that time, when there were no controls, protection was reported in from 90 to 100 per cent of the children¹ to whom doses varying from 50 million to "large" doses of $3\frac{1}{2}$ billion bacilli were administered. When controls were used,² the vaccine was found to have little or no prophylactic value.

Similarly, no complete prophylactic value was reported by Madsen³ in 1925 and 1933 in epidemics in the Faroe Islands in which doses of 22 billion bacilli

were employed. However, Madsen stressed the fact that the disease was milder and of shorter duration among the vaccinated and that the mortality in the vaccinated group was "one sixteenth of that in the nonvaccinated group." Sauer's⁴ reports since 1933 as to the prophylactic value of 80 billion bacilli seem convincing, except for the fact that he does not fully discuss his results in an adequate number of control children. The same criticism holds for the reports by others who have thus far published favorable results with his vaccine.⁵ This is unfortunate and detracts from the value of their work. Of significance in this respect is not only the experience of twenty years ago, as already mentioned, but particularly the recently published work of Doull, Shibley and McClelland.⁶ These investigators found that their whooping cough vaccine prepared of recently isolated strains and administered in a dose of 80 billion bacilli had virtually no prophylactic value, for they had almost as many occurrences among their vaccinated children three months or more after vaccination as among their control children. Their impression was that the disease tended to be milder among the vaccinated children.

In our study at Sea View Hospital we limited ourselves to a small group of children who were known to have had no past history of whooping cough. Approximately half of this group were given the

vaccine and the remainder were considered as unvaccinated controls. The vaccinations were begun in August 1934. The children received Sauer's authorized commercial vaccine in the recommended dose of 80 billion bacilli administered subcutaneously. The required dose of 8 cc was given in three successive weeks in divided amounts of 2, 3 and 3 cc as advised by Sauer. The vaccine was sent to us on the suggestion of Dr. Sauer. It had to be assumed that this vaccine authorized by Sauer fulfilled all the requirements established by him.

In an effort to maintain an approximately equal number of vaccinated children and unvaccinated controls of similar ages in each ward at all times, suitable children were selected for vaccination at varying intervals between August 1934 and April 1936,⁸ shown in table 1. About two thirds of the vaccinated children were under 6 years of age, the average age for the entire group at the time of vaccination was 31 years. There were eighty-two children designated as controls. Their average age was 27 years.

8 Dr. Bella Singer and Dr. Jeanne E. Shore aided in the administration of the vaccine.

Vaccinations were not given after April 1936, because an outbreak of whooping cough occurred during the late spring and early summer. The first case was diagnosed May 15 in a child, aged 3½ years, who was admitted May 1. The last case was recognized August 19. The duration of the epidemic period was about three and a half months. During this period there were twenty-seven occurrences of whooping cough in an exposed group of sixty-four children (42.1 per cent), 6 years of age or less. The high attack rate was expected, for the children were largely runabouts in close contact with one another during the day and exposed during the catarrhal stage when the disease is most communicable. Isolation was instituted in individual cases when symptoms suggestive of whooping cough were noticed. In all, thirty-three children were isolated. The characteristic whoop and lymphocytosis developed in twenty-seven children. These were considered as undoubted cases of whooping cough. Five other children had lymphocytosis and cough but no whoop. Since cough plate cultures were not made, the cases were considered as probable whooping cough. The remaining child had a cough which was associated with an exacerbation of his tuberculosis. Since there was no change in the lymphocytic ratio, he was not considered as having whooping cough.

TABLE 2—Age Distribution

Age in Years	Vaccinated Children	Controls

4	4	2
5	2	0
6	3	2
Total	17	19

For purposes of study, a grouping of the sixty-four exposed children showed that there were sixteen children with a past history of whooping cough, twelve children with a questionable history of whooping cough, and thirty-six children with no past occurrence of whooping cough.

Only the thirty-six children who were known to have had no past history of whooping cough were included in our study. The remaining twenty-eight children were excluded from our study because they had had whooping cough or their past history of whooping cough was either questionable or unobtainable.

There were seventeen vaccinated and nineteen control children among the thirty-six exposed children under consideration. There were fourteen boys and three girls in the vaccinated group and twelve boys and seven girls in the control group. The ages varied from 1 to 6 years. The average age for the vaccinated children at the time of vaccination was 2.8 years. At the onset of the epidemic the average age was 4.2 years for the vaccinated and 2.3 years for the nonvaccinated children. The age distribution in both groups at this time is given in table 2. The majority of the control children were less than 3 years of age, while the majority of the vaccinated children were 3 years of age or older.

The nature of the tuberculous lesion was quite similar in the two groups. There were eleven vaccinated and twelve control children with primary pulmonary tuberculosis, three vaccinated and two control children with hilar lymph node tuberculosis, one vaccinated and two control children with destructive pulmonary tuberculosis and one child in each group with tuberculous pleurisy with effusion. In addition,

one control child had miliary tuberculosis, and another had Still's disease, and one vaccinated child was a normal infant who had received BCG vaccination about six months prior to the whooping cough vaccination.

There were five characteristic cases of whooping cough among the seventeen exposed vaccinated children (29 per cent)⁹ and ten among the nineteen exposed control children (53 per cent). In all of these fifteen occurrences a paroxysmal cough, whoop and lymphocytosis were present.

As already mentioned, five other children in this group of thirty-six had a lymphocytosis and cough but no whoop. In the absence of cough plate cultures it was thought permissible to consider them as probable cases of whooping cough. They probably had an abortive form of the disease, which is not at all uncommon. Four of these children were vaccinated (24 per cent) and one was a control child (5 per cent). If characteristic and probable cases of whooping cough are combined, there were nine cases among the seventeen vaccinated children (53 per cent) and eleven among the nineteen control children (58 per cent). The clinical data relative to these twenty cases are shown in table 3.

The five vaccinated children in whom characteristic symptoms of whooping cough developed were from 2 to 3½ years of age at the time of vaccination. Their average age at the time of onset of whooping cough was 4 years, as compared with 2.5 years in the control group. The time interval between the completion of vaccination and the onset of symptoms of whooping cough was three months in one case, twelve months in three cases and sixteen months in another case. The types of tuberculous lesions in these five cases were primary pulmonary tuberculosis (three cases), hilar lymph node tuberculosis (one case) and destructive pulmonary lesion (one case). The attack of whooping cough seemed to have no apparent ill effect on the pulmonary tuberculosis in any of these cases.

The ten nonvaccinated control children in whom characteristic symptoms of whooping cough developed varied in age from 1 to 4 years, their average age at the onset of symptoms was 2.5 years. The types of tuberculous lesions in these ten cases were primary pulmonary tuberculosis (six cases), destructive pulmonary lesion (two cases), hilar lymph node involvement (one case) and miliary tuberculosis with extensive pulmonary tuberculosis (one case). The attack of whooping cough seemed to have no apparent ill effect on the pulmonary tuberculosis in any of these control cases except for one case (table 3, case 6), in which the development of whooping cough might have hastened the death of the child.

Among the five children who have been grouped separately as probably having whooping cough, there were four vaccinated children and one control child. Three of the four vaccinated children were less than 2 years old at the time of vaccination. All the vaccinations were given in December 1935, about seven months before the onset of symptoms.

An accurate evaluation of the severity of whooping cough in the group of children with characteristic symptoms is quite difficult. The disease was mild in most of the children. It was of moderate severity in one vaccinated child (case 1) and in several control children (cases 8, 9, 10 and 11). One control child (case 6) died of miliary tuberculosis and extensive

⁹ Since the totals are small the calculation of percentage is only a rough estimate.

pulmonary tuberculosis, which antedated the onset of whooping cough. In view of his extensive tuberculosis it was impossible to determine accurately the severity of the whooping cough or the effect on the tuberculous process.

In two of the children who were vaccinated the disease was very mild (cases 2 and 3). The average duration of the whoop was twenty-one days among the vaccinated children, as compared with thirty-two and a half days among the controls.

The average number of days during which the whoop was considered severe was two and eight-tenths days among the vaccinated as compared with seven and a half days among the controls. The disease, therefore, seemed somewhat milder among the vaccinated children.

Furthermore, there were fourteen vaccinated and twenty-four nonvaccinated control children over 6 years of age in the hospital during the epidemic, but they were not exposed to the disease. There were obviously no occurrences in this group, and they can be omitted from our discussion.

In addition, seventy vaccinated children and thirty-nine nonvaccinated control children had been discharged from the hospital before the onset of the epidemic. We succeeded in locating forty-six vaccinated children and twenty-two nonvaccinated controls. Of these, there were no known exposures to whooping cough and only one occurrence. In a nonvaccinated child whooping cough developed in September 1936, at the age of $3\frac{1}{3}$ years, six months after his discharge.

* Refers to the age in years at the onset of symptoms. The numbers in parenthesis refer to the age at the time of vaccination.

than it did among the controls. The age of the children might have been a factor here, for all the vaccinated children in this group were 3 years of age or older, while eight of the ten control children were less than 3 years of age.

Twenty-eight exposed children were excluded from the study because they had had a past history of whooping cough (sixteen children) or because their past history of whooping cough was doubtful or not obtainable (twelve children). Their ages varied from 1 to 6 years, the average being $4\frac{1}{2}$ years. There were eleven occurrences of typical whooping cough among these twenty-eight children (39 per cent). Five occurrences were among the sixteen children (31 per cent) with a past history of whooping cough. We do not know whether these cases are recurrences, for we are often doubtful of the diagnosis of whooping cough in the past history of our tuberculous children, because the paroxysmal cough of tuberculosis is frequently mistaken for whooping cough. There were six occurrences among the twelve children (50 per cent) in whom the past history of whooping cough was doubtful. The disease was mild in most instances. There were no complications.

from the hospital. Little significance can be attributed to the absence of whooping cough in the discharged vaccinated group of children because there was no known exposure.

COMMENT

The relatively high incidence of whooping cough among our vaccinated children exposed to whooping cough in the wards might be due to (1) the presence of active tuberculosis in the vaccinated children, (2) the presence of a particularly virulent micro-organism or (3) the ineffectiveness of the vaccine in whooping cough prophylaxis.

There is at present no evidence to support the view that the presence of tuberculosis per se diminishes the effectiveness of whooping cough vaccines. Since there are no simple, reliable tests of immunity to whooping cough, the relationship of tuberculosis to whooping cough immunization remains obscure. By means of serologic tests it was found that tuberculous children under our observation responded to the whooping cough vaccine much like normal children. The complement fixation test¹⁰ was strongly positive one week

10. The serologic tests in these cases were performed by Dr. Manfred Weichsel of the Department of Bacteriology, New York University Medical College.

324 19566

after completion of vaccination and remained positive in tests done one month after the last dose of vaccine. These results are comparable to those obtained in normal children and indicate that the vaccine readily stimulated the formation of specific antibodies in our tuberculous children. Furthermore, in our vaccinations against a disease such as diphtheria, the results of which can be well controlled by a simple skin test, we have had no difficulty in immunizing our tuberculous children with diphtheria toxin-antitoxin or with toxoid, as determined by the conversion of a Schick positive reactor to a Schick negative reactor.

Another possibility in explanation of the failure of the vaccine is the presence of an unusually virulent micro-organism during the epidemic. There seems to be no evidence in support of this view. The disease was mild in most of the children. There were no complications and no deaths due to a severe attack of whooping cough.

It seems that the attack rate was high not so much because of the presence of tuberculosis or of an unusually virulent micro-organism but because of the high degree of exposure of incompletely protected children. This is seen in other acute infectious diseases. In measles, for example, Karelitz and Schick¹¹ pointed out the increased difficulty of protecting children under conditions of intensive exposure and the consequent need for larger doses of immune serum. Under the conditions of exposure that prevailed at the hospital, the authorized commercial vaccine in a dose of 80 billion bacilli was ineffective in preventing the development of symptoms. However, although the vaccine did not prevent the development of symptoms, it seemed to be of some value, because the symptoms were, on the whole, less severe and of shorter duration among the vaccinated children than among the nonvaccinated children used as controls.

In this discussion we have omitted the question of the duration of immunity after vaccination. In our

In a group of seventeen vaccinated and nineteen nonvaccinated tuberculous children intimately exposed in the hospital during the catarrhal stage of whooping cough, characteristic whooping cough developed in five (29 per cent) of the vaccinated children and in ten (53 per cent) of the nonvaccinated controls, while lymphocytosis and cough, but no whoop, occurred in four (24 per cent) of the vaccinated children and in one (5 per cent) of the control children (table 4). There were eight children without symptoms in the vaccinated group (47 per cent) and an equal number in the control group (42 per cent).

CONCLUSION

1. Sauer's authorized commercial vaccine, in a dose of 80 billion bacilli, did not seem to prevent the development of symptoms in a group of vaccinated tuberculous children exposed to whooping cough at Sea View Hospital.
2. The symptoms seemed, on the whole, to be milder and of shorter duration among the vaccinated children than among the nonvaccinated children used as controls.

NURTURING A NATIONAL NEUROSIS

CHARLES D. ARING, M.D.

CINCINNATI
AND

J. FREMONT BATEMAN, M.D.

COLUMBUS, OHIO

In this supposedly modern age of psychiatry it is indeed inconsistent and somewhat startling to find that the government of an enlightened country is foisting upon its citizens a state akin to a national neurosis. Reference is made to the manner in which the Veterans' Administration disposes of those individuals who come under its jurisdiction with ills that might be included under the heading of psychoneurosis.

We are uninformed whether or not a somewhat comparable situation developed, psychiatrically speaking, after previous campaigns involving this country. There is no reason to believe that such was not the case, but that the neuroses were encouraged and provided with such fertility in which to develop as they were after the World War is unlikely. It is probable that no precedent was set for the psychiatric confusion in which the Veterans' Administration now finds itself. The experience of other governments with this problem should not have been overlooked, for they had had three years of war behind them when the United States became involved, and their physicians had been stimulated thereby to numerous publications on such subjects as "war neuroses," "soldier's heart," "shell fright"¹ and the like (see especially Hurst,² Mott³ and Marr⁴ and particularly the references contained in the first two works).

The authors served consecutively as neuropsychiatric specialists in the Cincinnati Regional Office of the Veterans Administration for a period of fifteen months.

1. It has been suggested that if men suffering from shell shock had been labeled originally "shell fright" and made to wear a badge there would be far fewer of them today. A physician with one of the Scottish regiments has stated that the medical men of this particular regiment did not recognize shell shock with the result that the incidence of men presenting themselves with the signs of shell shock was reduced to near zero.

2. Hurst, A. F. *The Psychology of the Special Senses and Their Functional Disorders*. London: Oxford University Press, 1920.

3. Mott, F. W. *War Neuroses and Shell Shock*. London: Oxford University Press, 1919.

4. Marr, H. C. *Psychoses of the War Including Neurasthenia and Shell Shock*. London: Oxford University Press, 1919.

TABLE 4—Results Among Vaccinated and Nonvaccinated Control Children Exposed to Whooping Cough at Sea View Hospital

	Number of Exposed Children in Study	Effects of Exposure to Whooping Cough							
		Children with Characteristic Whoop		Children with Cough and Lymphocytosis		Total Number of Children with Symptoms		Children Without Symptoms	
		Number	Per Cent	Number	Per Cent	Number	Per Cent	Number	Per Cent
Vaccinated children	17	5	29	4	24	9	53	8	47
Nonvaccinated children	19	10	53	1	5	11	58	8	42

opinion, this problem has not been adequately studied. It is important, because active immunity produced by bacterial vaccine is short lived. It is advised, for example, that typhoid vaccination be repeated every two years. The long lasting immunity that follows recovery from an attack of typhoid or whooping cough does not indicate that an immunity of equal duration will result after vaccination.

SUMMARY

From August 1934 to April 1935, 101 tuberculous children at Sea View Hospital were vaccinated with 80 billion bacilli of Sauer's authorized commercial vaccine.

11 Karelitz, Samuel, and Schick, Bela. *Epidemiologic Factors in Measles Prophylaxis*. J. A. M. A. 104: 991 (March 23) 1935.

It is difficult to believe that the government made practically no provision for the treatment of what was to be one of the most disabling of the illnesses arising out of the late war (table 1). This is especially noteworthy in light of the rise of psychiatry and the spread of psychotherapeutic technic into medical consciousness which occurred before the war. Possibly rules were made to cover (considering the political penchant for making rules), but they never reached fruition, they got no further than the rule books and so did nobody good except possibly those who drew a salary for spreading them on the records.

A veteran may present himself with appendicitis and have the appendix removed at the expense of the government years after he served in the army, and the same holds true for remedial measures directed against any of the physical ills that beset man.⁵ But let him present himself with a neurosis, be it mild or severe, and he is treated generally speaking by the methods in vogue a hundred years ago if at all. The attitude that permeates the veteran facilities as regards the neuroses is indeed a pitiful one and we believe has developed gradually for several reasons which will now be discussed.

In formulating the regulations for the compensation of disabilities arising from the World War, an omnipotent individual or group of individuals decided that all cases of psychoneurosis "of 10 per cent or more" originating within five years after the close of the war were "service connected," that is, the illness originated or was augmented as a direct result of service in the armed forces and therefore an individual so affected should be compensated.⁶ On the basis of this ruling it can be seen without too much thought that a veteran with a psychoneurotic disorder must be compensated regardless of when the disabling symptoms made their appearance. No one of us can remember any period of months in his life during which he was entirely free from "nervousness," and all of us should be able to produce reasonable affidavits (medical and lay) proving the fact. This becomes increasingly simple when one has numerous acquaintances and is handling implements of war. Disregarding the verbiage quoted and descending to sound psychiatry, all life experience contributes

to the psychic organization of the individual, and if a neurosis develops any time after serving in the forces, this service can be said to have contributed to the disorganization. There is no point in delving into the question of how much was contributed toward the psychoneurotic state by three months in an army camp or a year on the battle fields, or by school and occupational experiences for that matter. Despite the occult powers assumed by some psychiatrists (experts found wandering but still capable of speech⁷) it is doubted that the reasonable members of the order would be willing to be judged by a statement that a specific

* Results of 556 examinations performed from April 6 1936 to April 5 1937 by the neuropsychiatrist at the Cincinnati Regional office. These examinations were for compensation for insurance or for the purpose of referral to a hospital and do not include those patients seen as outpatients. They do include a few veterans of the Spanish American War. It will be noted that 43.3 per cent of all the cases showing a neuropsychiatric disorder were theoretically amenable to psychotherapy (those under the heading psychoneurosis). This figure compares with 35.7 per cent which is derived by tabulating for a three months period the diagnoses from other government facilities who forwarded their records to the Cincinnati Regional office for rating.

experience did or did not augment or originate the psychoneurosis. That the specific experience, regardless of what it was, did contribute there cannot be much doubt.

Continuing the fallacious reasoning noted in the first portion of the foregoing paragraph the Veterans' Administration decided that psychoneurotic individuals were divisible into three great groups, namely, severe, moderate and mild (and should be compensated accordingly), depending on the amount of social and industrial incapacity caused by the illness, disregarding the individual psychobiology. It is not difficult to see what this ruling connotes. This was a definite step toward fixing the neurosis, toward making certain that it would never be amenable to treatment, in fact, it was the one infallible manner in which the administrators could be sure that the illness would be progressive. If the monetary reward is the greater the more severe the neurosis, what has the psychiatrist to offer in comparison?

5 The following statement by Pearsall of the Milwaukee facility of the Veterans Administration is to the point. I often wonder if veterans realize the magnificent insurance policy they hold with the government. An honorable discharge qualifies a veteran to go to a government hospital stay as long as necessary and if he passes on his funeral expenses burial etc. are all taken care of by Uncle Sam. If at the end of the hospital period he is unable to return home, he can go into domiciliary care. His transportation is paid both to and from the hospital and that of an attendant if necessary. While in the hospital he goes through one of the finest medical clinics in the country equipped with the latest modern equipment, and receives care from superior doctors nurses and other trained personnel. While there if necessary he is provided with good clothing cigarettes or smoking tobacco razor brush and comb tooth brush tooth paste shaving cream and soap and numerous other articles. He has a marvelous library at his disposal frequents entertainments of the highest order and all this without the worry of how the bill is to be settled. To me government hospital care is so superior that I would never consider entering even the most expensive hospital in the country. An insurance policy covering all the benefits given us by the government is not obtainable for any amount of money and if one were, doubtless few of us would be able to pay the premium of such a policy as it necessarily would have to cost very high. All veterans should think deeply of this advantage and feel grateful and thankful to our government for its thoughtfulness of us.—Pearsall, C. M. The Value of Benefits Enjoyed by Veterans. M. Bull. Vet. Admin. 13 372 (April) 1937.

6 The following is the ruling. The presumptive service connections have their origin in the amendment of August 9 1921 (42 Stat 147) which is an effort to bring within the law (War Risk Insurance Act) those veterans who were suffering with pulmonary tuberculosis and neuropsychiatric diseases who could not produce sufficient evidence to show direct service connection, provided that if they could show that they suffered from these diseases to an extent of 10 per cent disability within two years after separation from the service they should be considered to have acquired the disease in service. This presumption was later extended by the amendment of June 7, 1924 so that veterans with certain diseases (tuberculous and neuropsychiatric) which developed to a disability of 10 per cent degree or more prior to Jan 1 1925 are presumed to have incurred the disease in the military or naval service.—Federal Laws Relating to Veterans of Wars of the United States. Senate Document 131 Aug 2 1932.

24 19566

Various veterans' organizations (Disabled Veterans of the World War,⁸ American Legion, Veterans of Foreign Wars) and the Red Cross⁹ have welded the second link of this chain. The veterans' organizations solicit the membership of veterans of the World War and will assist all veterans in the preparation of their claims for compensation, representing them before rating boards. They must of necessity use every legal device at their command to obtain compensation for their clients, and they are constantly exerting every pressure direct and subtle to have compensation awarded, or increased, and at the very least not decreased. One method utilized in an effort to increase compensation is to attempt to have so-called non-service connected disabilities which are not compensable classified as being due to that portion of the disability that is rated as "service connected." For example, if a veteran who has been compensated for psychoneurosis acquires some other condition years later, say hyperthyroidism, an attempt might be made to rate the thyroid condition as due to the psychoneurosis, the compensation for "services connected" disability being increased accordingly. This is but an example, however, the direct and precipitate factors incident to diseases peculiar to veterans and the element of time existing between them would make interesting reading but we haven't the space for this diversion. The veterans' organizations have taken the apparent stand, indirectly it is true, that nothing is curable (i.e., that the amount of compensation should never be reduced). Whether or not they have transmitted this attitude to the rating boards (it must be stated that we had direct experience with the functioning of the Cincinnati rating board only) is not known, if not, it has been developed spontaneously there. The board is always willing to award or increase compensation, to decrease it, as a rule, is a very involved procedure.¹⁰ This influence is especially pernicious among individuals suffering from illnesses of a purposive nature, an improvement in their condition under these circumstances is out of the question.

8. Seemingly the only qualification one must have to gain admittance to this organization is a disability after having served in the forces during the World War. One of us attempting to determine what a veteran an imbecile did with his time and whether or not he was completely asocial was amused to hear him declare that he had many friends that the D A V were constantly writing to him asking why he didn't show up for their meetings.

9. That a national organization supported entirely by private subscription should be spending some of its funds and time attempting to obtain compensation for veterans seems rather peculiar at first sight. But it must be remembered that Congress has declared the responsibilities of the Red Cross to be the service man, the ex service man and the population in localities of disaster. Their point of view may be grasped when it is realized the Red Cross extends an interval type of relief to any veteran not entitled to relief from other agencies until some other more permanent arrangement can be secured for the veteran. The most permanent and possibly that most readily obtainable is compensation on the basis of some disability the Red Cross taking up the chore of proving it service connected which is the only type of disability compensable under the present laws [Disability allowance [as differentiated from disability compensation] provisions were enacted by the amendatory act of July 3 1930 [46 Stat 993]]. This measure constitutes a departure from the theory upon which the original World War veterans relief legislation was based in that it affords monetary benefits to veterans whose disabilities are not the result of service in the World War. This is as follows:

Any honorably discharged ex service man who entered the service prior to Nov 11 1918 and served ninety days or more during the World War and who is or may hereafter be suffering from a 25 per cent or more permanent disability as defined by the director (administration) not the result of his own wilful misconduct which was not acquired in the service during the World War or for which compensation is not payable shall be entitled to receive disability allowance of the following rates: 25 per cent disability \$12 per month 50 per cent disability \$18 per month 75 per cent disability \$24 per month total permanent disability \$40 per month.—Federal Laws Relating to Veterans of Wars of the United States Senate Document 131 Aug 2 1932.

10. The following note from the rating board (which consists of a physician an attorney and a lay individual) illustrates the point. To the neuropsychiatrist. The board notes that the examiner states that the disability psychoneurosis is temporary. The board wishes to know if a social service report was considered when making this statement. It shows more or less nervous trouble over several years time. Your opinion is desired before completing the rating.

Veterans' hospitals are scattered over the United States and all of these institutions have one or more neuropsychiatrists on their staffs. These physicians and hospitals are admittedly unequipped to care for the veteran with a neurotic disorder under the present state of affairs, for these individuals are discharged from these institutions after the diagnosis of psychoneurosis is made with the unfailing recommendation that treatment is not advised. This is a natural development under the handicap with which they work.

Despite the thoroughness with which the Veterans' Administration has gone about fostering neurotic disorders in their charges, one occasionally meets a veteran who has not become completely dominated by the situation and who desires help. He may be sent to a veterans' hospital¹¹ where he may receive bromides or phenobarbital, or he may visit the neuropsychiatrist at the regional offices as an outpatient and receive the same treatment. A veteran with psychoneurosis having myriad somatic complaints said that he had been ill since leaving the army (about eighteen years ago) and that he had been in numerous government hospitals and had had seventy x-rays, yet only once did a physician mention the possible mental origin of his difficulties. He was receiving \$100 monthly (for permanent and total,¹² "service-connected" disability) and that was all the Veterans' Administration had to offer him. This case is not at all unusual. A hernia may be repaired and syphilis cured, but the neuroses are only magnified under the present system and in fact are treated no better than they were a century ago.

THE MAZE OF GOVERNMENT EXAMINATIONS

It is interesting, albeit time consuming, to follow the ramifications of one of these individuals through the maze of government examinations (since treatment). This does not include the numerous examinations by private physicians for the purpose of furnishing affidavits. The following case is not at all unusual. The story begins at the Verdun front, where the veteran's left leg was damaged by a solid shell. Amputation was performed at the middle third of the left thigh Oct 11, 1918, at a French hospital. At the time of discharge, March 18, 1919, it was noted that an artificial limb had been fitted and that the patient was proficient in its use. He was receiving \$25 monthly compensation for the loss of the limb. On April 25, 1919, it was noted that he had been unable to use his left arm for a long period following blood transfusion after the amputation, fair warning of what was to follow. During the remainder of 1919 and 1920 he was periodically examined at a government hospital, especial attention being given to the stump and artificial leg. In December 1920 a reputable neurologist noted that the veteran was suffering from "mild psychasthenia." It was noted that he complained of insomnia, headaches, nervousness, inability to concentrate and a sensation resembling that of "insects crawling" over

11. These institutions usually refuse to admit veterans with psychoneurosis within a short time after their discharge from a hospital because they have received maximum benefit from hospitalization.

12. It might be well at this point to note that a patois (possibly better termed a lingo) has evolved in government service which is a model of prolixity and circumlocution although the users believe it definitive. Thus permanent and total disability rarely means what it says for one is often able to reach permanent and total disability yet remain able to carry on a productive and gainful occupation or be suffering from a reliable illness (e.g. psychoneurosis). For example a physician once drew maximum compensation for disability and at the same time practiced on a full time basis in a hospital. Some controversy ensued and the disability remuneration was discontinued as it was less than his salary. If however this individual relinquishes the practice of medicine he can receive immediate permanent and total disability benefits because of his illness.

his body. There then followed the examinations at regional offices and hospitals of the Veterans' Administration as shown in table 2.

At the time of the last examination the veteran was receiving disability compensation of \$125 a month. He was told that he was fit at one of the latter examinations and on that basis thought he might get insurance but was refused by one of the large life insurance companies. In passing it is noted that he is unable to name a single thing that he does to pass his time. It should not be difficult to visualize the confusion in

TABLE 2—Government Examinations of a "Neurotic" Veteran

Date	Diagnosis	Recommendation
12/14/20	Psychasthenia	Sedative physical therapy

which such an individual finds himself, and we will pass over these details. Buffeted about, having his "reward for illness" periodically raised and lowered in amount for no apparent reason (actually on the basis of the diagnoses) and told nothing about the nature of his illness, he soon becomes a fairly useless individual as far as society is concerned.¹³ It should be repeated for emphasis that this is not an unusual record of a "neurotic" veteran.

13 The following letter is from an invalid psychoneurotic veteran who could probably be relieved in one's psychiatric practice yet is "permanently and totally disabled as far as the Veterans Bureau is concerned."
U S Veterans Bureau Dear Sir—In reply to your letter asking me to be sent to the Hospital I know my neural condition and I am sure the clinical examination would be more than I could stand. It is not that I don't wish to comply with your request but that I would feel safer at home. It may be some kind of phobia. I seldom get out of sight of my wife—she seems to be my perfect sedative.

The family life of veterans suffering from psychoneurosis was inquired into both from the veteran and from the wife who occasionally accompanied them. These veterans as a rule report their families well and happy, but their wives tell a different story. It is not unusual for the wife when queried in private to note that a child is "just like his father," with many of the same somatic complaints, fears, food fads and addiction to medicines, and express rather indirectly her own dissatisfaction. This seemed significant, although we have no statistical data on the subject. It would well form an excellent subject for investigation. It is a remarkable fact that the majority of these men assume the additional responsibility of a wife (repeated marriages seemed quite high in these veterans) and numerous children, despite the lack of energy and numerous complaints leading to invalidism or semi-invalidism. We hold no brief for the strict environmentalist, but children raised in the enervating atmosphere created by these individuals are certainly not bettered by it. Imitation of parents is a large and recognizable factor in the mental development of all of us. The onus for sponsoring a national neurosis therefore is not too large an indictment, when one considers what is taking place in our national life as a result of this unenlightened method of the treatment of a large group of the psychically ill.

RESPONSIBILITY FOR THE SITUATION

Is the Veterans' Administration, whose budget runs about one-half billion dollars yearly, solely responsible for this deplorable state of affairs? The hand of the bureaucrat is evident in no small measure.

What of the physician in the full term service of the government? A *laissez faire* attitude is easily developed in this atmosphere which is extremely enervating, as the work and even the complaints of clients become unusually routine. It would be our thought that this is possibly the case under any political system of organized medicine, where everything is done in a predetermined manner and according to rules that are along mathematical rather than medical lines, where everything is settled and down to percentage figures, and where initiative and originality are stifled because of the set precedent or stereotyped manner which determines the method of procedure. It might be well to survey the amount and quality of investigative work coming from the Veterans' Administration as a rough index of initiative under regimentation. Griffith, the medical director of the Veterans' Administration, in the preface to the medical bulletin issued quarterly by this organization, notes in speaking of the Veterans' Administration and its Bulletin, and the opportunities for research and study within the organization, "It is evident that the field for investigation is unlimited, and that the opportunity to make helpful application of the conclusions reached is unprecedented." If this is true and when it is realized that physicians in these posts have more leisure than their practicing or academic colleagues, it would seem that they should be as productive if not more productive than their unregimented practicing colleagues, other factors being equal.

Does the veteran himself carry any responsibility for the situation? He and his representatives know that it exists and could remedy the condition if they so desired. But the individual point of view is so short sighted that it fails to see that his birthright, which consists chiefly of good health, is being frittered away for a mess of pottage. Perhaps the majority are com-

224 19566

pletely uninterested, if so, their alleged representatives, their organizations, should interest themselves in the situation

A great deal of responsibility must be laid at the door of the practicing physician. It would amaze those who set too high a store on the ability and integrity of physicians as a whole to read some of the ridiculous statements which they give to their veteran patients or send to the Veterans' Bureau. A great many of the records of veterans contain statements from practicing physicians which are either falsifications or direct evidence of incompetence. Some practicing physicians, like our government, rate their patients' disability in exact percentage figures and more often than not find corroborating evidence (which does not exist) for claimed disabilities. This evidence cannot be waived as coming from "quacks"¹⁴ and "charlatans,"¹⁴ for although that would be the inference, the Veterans' Bureau does not accept medical, documentary evidence from other than licensed physicians.

PROCEDURE FOR THE FUTURE

What remedies are there to be offered to alleviate the present conditions or, to be a bit more practical, what should the procedure be when the situation again arises?

First, cases of psychoneurosis in veterans should be recognized early and treated properly. To assist the bureau in the determination of difficult cases, recognized specialists should be appointed to give an independent opinion on the complete evidence. This method is used by the English Ministry of Pensions¹⁵ and is in vogue at the Veterans' Facility at Hines, Ill., whence comes some of the more valuable medical opinion rendered in the Veterans' Administration. We do not mean by the term specialist some one who has assumed the title. Those who are diplomats of the American boards or on the faculties of medical schools would be desirable.

Since experience has proved that the Veterans' Administration is not capable of properly treating psychoneurotic veterans, some method for their early treatment should be devised. We would think that this treatment might be best carried on by psychiatric practitioners on a fee basis. This does not mean that these patients should be referred to any physician at a nominal fee, as is now occasionally done, but rather they should be sent to those trained in the handling of the psychoneuroses, and at reasonable fees to attract competent men. This would entail no more expense than the present method over a period of years.

The problem of disability compensation is indeed a knotty one. There is little argument against the fact that if veterans suffering from psychoneurosis were not compensated they would be better off socially, the community would be benefited and there is no doubt that they would then be amenable to psychotherapeutic measures. In the present state of affairs it probably would be best to admit no more men to the compensation rolls as psychoneurotic, and to fix some unvarying sum to be paid for life as just compensation to those already there. If the "disability compensation" were made permanent there would no longer be that insuperable barrier to rational treatment. Should the same situation arise in some future year, it would be well to limit disability compensation for psychoneurosis

to those shown to be disabled at the time of discharge from the service. Their number probably could be limited by competent entrance examination, but we would be the last to advocate that the soldier should be only the intellectually normal and mentally well integrated individual. We would lay the stress on the discharge examination, when the tension and rush are less and the opportunity to make a reasonable evaluation of the individual is in direct proportion to the examiner's ability. It would undoubtedly pay in the long run to have qualified opinion on the disabled individual and those claiming disability at that time. Belated applications for aid of course would be received under any system, but the aid given could be limited in all fairness to that noted in footnote 5. Surely this would constitute sufficient reward for doing one's duty.¹⁶

We would also recommend that veterans and especially the veterans' organizations be educated to the fact that the psychoneuroses are relievable and not "permanent and total" disabilities, as they seem to believe. It might also be well to invoke the fine and jail sentence for false statement against the physicians, veterans and their representatives who are deserving of them.

It appears that the tremendous financial outlay could be reduced and much suffering relieved by the use of reasonable methods. We have not gone into financial matters because of lack of space, but we recommend comparison of statistics from the British Ministry of Pensions and those of the United States Veterans' Administration. It will suffice for the medical reader to note that as Great Britain's expenditure for veterans steadily decreases, that of the United States rapidly increases. Lest the impression be derived that we are advocating a general reduction or discontinuance of disability compensation, let us settle this matter. We are of the opinion that those disabled in service cannot be compensated too much, regardless of the cause of the disability. We see no reason to cause directly or nurture disability by political methods after the cessation of service. Much of the medicine as practiced by the Veterans' Administration seems to us analogous to what may be expected under any regimented practice. Possibly we have here a "prevue" of state medicine, medicine as it is administered by politicians. It might be well for physicians to anticipate and originate any changes that are to be made in the future of the profession and thereby keep the administrative reins where they belong, in the hands of physicians instead of politicians. If the psychiatric service (this does not refer to custodial care) of the Veterans' Administration is any criterion, the former is to be preferred.

¹⁶ See Foster Kennedy's letter to the New York Times in 1935. He has noted that in times of war it is the duty of the able-bodied men to defend their country. In times of war and peace it is the duty of able-bodied women to bear male children to defend the country. If one group is to receive special consideration monetary or otherwise for doing their duty the other should have it on the same basis. Dr. Kennedy's handling of the subject is most adept and we recommend its perusal.

The Galileo of Psychology—But, at present psychology is in the condition of physics before Galileo and the laws of motion, of chemistry before Lavoisier and the notion that mass is preserved in all reactions. The Galileo and the Lavoisier of psychology will be famous men indeed when they come, as come they one day surely will, or past successes are no index to the future. When they do come, however, the necessities of the case will make them "metaphysical"—Paget, Stephen *Confessio Medici*, New York, Macmillan Company, 1931.

¹⁴ We use these terms in the manner in which they are usually employed by organized medicine.

EFFECT OF CERTAIN GYNCOLOGIC LESIONS ON THE UPPER URINARY TRACT

A PNEUMOGRAPHIC STUDY

HERMAN L. KRETSCHMER, M.D.

AND
AARON L. KANTER, M.D.

CHICAGO

In several previous communications, one of us¹ in collaboration with Heaney and Ockulv studied by means of retrograde and intravenous pyelograms, the changes that occurred in the upper urinary tract during pregnancy and the puerperium. It was demonstrated in these studies that during pregnancy and the puerperium dilatation of the ureters and kidney pelves occurred in 100 per cent of our cases that there was a return to normal in 59.3 per cent after two weeks and in 34.3 per cent after six weeks and that the remaining 6.2 per cent were normal after twelve weeks. The striking fact about the dilatation of the ureter during pregnancy is that with rare exceptions it is above the brim of the pelvis. Another point emphasized by these studies was that lateral displacement when found early in pregnancy, tends to increase as the pregnancy advances. Many contributions have since verified these observations.

With these facts in mind, it occurred to us that it might be instructive and profitable to study a group of nonpregnant women who were suffering from various lesions of the gynecologic tract in order to obtain answers to the following questions:

1. Do changes in the upper urinary tract occur in association with lesions of the pelvic organs in women?
2. How frequently do they occur?
3. Is there any definite relation between the type of disorder in the pelvis and the lesions in the upper urinary tract?
4. In what way, if any, do the changes resemble changes found during pregnancy?
5. Do these changes completely disappear after the pelvic disorder has been corrected by the appropriate surgical measures?

SELECTION OF CASES

In the selection of cases for this study we used patients who had no urinary symptoms and who were normal on urinary examination so that we might demonstrate how frequently changes are found in this so-called silent or asymptomatic group. In cases in which there were urinary symptoms, attention is naturally directed toward the urinary tract hence changes, when present, are readily found. However, if a group of patients have no urinary symptoms changes in the upper urinary tract when present may be readily overlooked.

In view of the fact that we are also interested in trying to demonstrate whether changes in the kidneys and ureters disappear after appropriate gynecologic operation, a statement should be made that cases presenting carcinoma were not included for the following reasons: 1. It is well known that in cases of carcinoma

of the cervix, obstruction to the ureter occurs with great regularity. This has again been recently emphasized by Graves, Kickham and Nathanson³ who found obstruction in more than 70 per cent of their cases. 2. In view of the fact that the lesion in cases of carcinoma cannot be so completely removed as in other types of disease and hence changes in the upper urinary tract do not completely disappear as in cases in which the pathologic condition can be removed, we felt that cases of carcinoma were not desirable for the purposes of our study.

Isolated case reports of changes in the kidneys and ureters, associated with various lesions in the pelvic viscera have been reported but we have been unable to find papers in which large groups have been studied both before and after operation.

We carried out intravenous pyelography as a routine, using diodrast in 20 cc and 30 cc ampules.⁴ This was

Fig 1 (case 1 fibroid above the brim of the pelvis)—Preoperative pyelogram taken April 5, 1937 showing marked dilatation of the lumbar ureter. Note difference in size between the right and the left pelvis.

supplemented by retrograde pyelograms in a few instances in which the intravenous method was not satisfactory or in which we wished to check the results of the intravenous pyelograms.

TYPES OF PELVIC DISORDER

In table 1 are presented the various types of gynecologic disorders that were found in this group of cases. *Fibroids Above the Brim of the Pelvis*—There were twenty-four cases of fibroids above the brim of the pelvis. Of these twenty-four cases, seventeen demonstrated a pathologic condition in the upper urinary tract whereas seven were completely normal. Six of these twenty-four cases showed unilateral right-sided dilata-

tion, two unilateral dilatation with lateral displacement of both ureters, three bilateral dilatation, three bilateral dilatation with unilateral lateral displacement, and one bilateral dilatation and bilateral lateral displacement and in two there was displacement alone, unilateral in one, bilateral in the other, with no dilatation

Fibroids Below the Brim of the Pelvis—There were eleven cases of fibroids below the brim of the pelvis. In this group six presented pathologic changes in the pyelogram and five were normal. Three of these eleven cases showed unilateral dilatation, on the right side in two cases and on the left in the third, one unilateral dilatation with unilateral lateral displacement, one bilateral dilatation, and one bilateral dilatation with bilateral lateral displacement.

Fig. 2 (case 1)—Postoperative pyelogram taken April 24 showing normal condition.

Ovarian Cysts—In this series there were eleven cases. Nine showed changes in the upper urinary tract and only two appeared normal. In four cases there was unilateral dilatation (three on the right and one on

TABLE 1—Types of Gynecologic Disorders

Condition	Cases

Tubo-ovarian abscess	1

the left side). In one case there was unilateral dilatation with unilateral lateral displacement, in three cases bilateral dilatation, and in one bilateral dilatation with unilateral lateral displacement.

Prolapse—Of the four cases of prolapse, three appeared normal and only one showed bilateral dilatation.

Tubo-Ovarian Abscess—In the one case of tubo-ovarian abscess the pyelograms were negative (table 2).

CHANGES IN THE PYELO-URETEROGRAM

Pyelogram—The changes varied in degree from unilateral dilatation of the pelvis alone or dilatation of the pelvis and calices to very extensive dilatation and clubbing of the calices.

Ureterogram—The changes in the ureters consisted of unilateral or bilateral dilatation and unilateral or bilateral displacement of the ureters or a combination of the two.

It was interesting to note that, irrespective of the type of gynecologic lesion present, the dilatation when found, was above the brim of the pelvis, with the exception of the one case in which the pelvic ureter was dilated down to the vesical end (case 2, figs 1 and 2). In this case a diagnosis of true stricture of the ureter

TABLE 2—Observations on Piecemeal Pyelo-Ureterograms

	Fibroids Above Brim of Pelvis	Fibroids Below Brim of Pelvis	Ovarian Cysts	Prolapses	Tubo-Ovarian Abscess	Total

at the vesical end was made, and so it undoubtedly does not belong in this category of cases and will be discussed further along in the paper.

THE RESULTS

The largest percentage of changes in the upper urinary tract was found in the cases of ovarian cyst, out of a total number of eleven cases, changes in the pyelo-ureterograms were noted in nine cases, or 81.8 per cent. It would appear reasonable to assume that the high incidence of changes in the upper urinary tract in ovarian cysts is probably due to the fact that the cysts, being of soft consistency, readily mold themselves into the pelvis, which results in pressure on the ureters, as seems to be the case in pregnancy. If the two very high-lying intra-abdominal ovarian cysts are excluded which because of their position, could not possibly have compressed the ureter, it is found that the ovarian cysts produce changes in the upper urinary tract in 100 per cent of the cases. Therefore it would be reasonable to assume that the consistency of the tumor and its ability to mold or compress has something to do with the high incidence of the changes in the upper urinary tract.

In the large fibroids above the brim of the pelvis 70.9 per cent showed changes in the ureteropyelograms. When the lateral displacement of the ureter was bilateral the uterine enlargement was mainly in the midline (case 3, fig. 3). In the case in which there was unilateral displacement, the growth of the tumor corresponded to the side of the displacement.

Of the large fibroids above the brim of the pelvis in which there was no dilatation of the upper urinary tract, it was found at operation that the fibroid growing out of the pelvis left a free interval between the tumor and the brim of the pelvis, so that there was no pressure on the brim of the pelvis. In the cases in

case it was impossible to get the patient back to the hospital for a check-up. It is interesting to note at this point that in the one instance in which the marked lateral displacement did not return to normal it is possible that the interval between the operation and the intravenous pyelographic study was too short to obtain a complete return to normal. In this connection we wish to state that, in some of the cases that showed the presence of slight changes two weeks after the operation, subsequent study two or three months later showed

TABLE 3—Observations on Postoperative Pyelo-Ureterograms

	Fibroids Above Brim of Pelvis	Fibroids Below Brim of Pelvis	Ovarian Cysts	Prolapses	Tubo Ovarian Abscess	Total
Complete return to normal	1		7	1		24
Partial return to normal	2	1	1			4
Marked improvement			1			1
No change	1	1				2
Not in for check up	1	1				2

a complete return to normal. In the few instances in which there was no return to normal, it is possible that inherent ureteral pathologic changes were present, although no symptoms and no changes in the urine were evident.

Fig. 3 (case 3 large fibroid above the brim of the pelvis)—Preoperative pyelogram taken April 13, 1937 showing marked lateral displacement of the left ureter and displacement and angulation of the right ureter. The right pelvis shows slight dilatation.

which there was dilatation, it was found at operation that the fibroid so molded the pelvis that it probably compressed the ureter with resulting dilatation. In one case the dilatation was limited to some of the calices and rapidly disappeared after operation. Therefore it is reasonable to assume that pressure seemed to play a role in dilatation because the dilatation disappeared after the fibroid was removed.

In a review of fibroids below the brim of the pelvis, in table 2, changes in the upper urinary tract were produced in six out of eleven cases. Since, in the cases selected, the fibroids were in no instance smaller than a three months pregnancy, the same role in the production is possible.

STUDY OF THE POSTOPERATIVE URETEROPYELOGRAMS

In table 3 are presented the results of the study of the pyelograms made after surgical operation to determine whether the changes shown preoperatively are permanent or whether they disappear after the pathologic condition is corrected. Postoperative pyelograms were made with the results shown.

Of the patients with fibroids above the brim of the pelvis showing changes in the ureteropyelograms thirteen showed a complete return to normal. Of the four instances in which there was no return to normal, slight dilatation persisted in two, a certain amount of lateral displacement persisted in one and in the fourth

Fig. 4 (case 4 right ovarian cyst)—Preoperative film taken Nov. 12, 1935 showing double kidney and double ureter on the right with marked dilatation. Note extreme dilatation of the right lumbar ureter.

Of the six cases showing pathologic changes below the brim of the pelvis and changes in the ureteropyelograms, in three there was an immediate return to normal after operation. One case showed no improvement—a true bona fide stricture of the ureter—and in one case there was marked looping of the ureter,

in the third it was impossible to obtain a postoperative pyelogram. In one instance preoperative pyelograms were normal, postoperative pyelograms showed dilatation and subsequent pyelograms showed a return to normal.

In the group of ovarian cysts, of the nine cases that showed changes in the ureteropyelograms before operation there was a complete return to normal in seven within twelve days after operation. Of the two patients who did not completely recover, one showed marked improvement, and we believe that with a further passing of time recovery will be complete. In the second case there was marked postoperative improvement but no complete return to normal. In this instance a congenital anomaly was present, namely, a double kidney.

Fig. 5 (case 4)—Postoperative pyelogram taken November 23 showing marked improvement but not complete return to normal.

with a double pelvis, and it is possible that the presence of the congenital anomaly accounts for failure to return to complete recovery.

SUMMARY AND CONCLUSIONS

1 It would appear that the incidence of secondary changes in the upper urinary tract in association with various types of gynecologic disorders is high. In this series of fifty-one cases, evidence of changes in the upper urinary tract was found in 64.7 per cent. In the group of fibroids, changes were found in 65.7 per cent, in ovarian cysts, 81.9 per cent, in prolapses 25 per cent, in the one case of tubo-ovarian abscess there was no change in the upper urinary tract.

2 Failure to appreciate the frequency with which these lesions occur is due to the fact that there has been no routine preoperative study in the group of cases that do not present urinary symptoms and urinary signs.

3 Following appropriate surgical procedure a return to normal takes place in 72.5 per cent.

4 Subsequent pyelograms should be carried out in all cases in which recovery has not occurred at the time the patient is discharged from the hospital.

122 South Michigan Avenue

ABSTRACT OF DISCUSSION

DR ROSEMARY SHOEMAKER, Rochester, Minn. This paper has presented a group of cases which are too often overlooked because of lack of symptoms. In considering the mechanism of dilatation of the ureter in these cases I would mention three etiologic factors: atony, mechanical obstruction, or obstruction resulting from intrinsic inflammatory changes in the ureteral coats or extrinsic inflammatory changes surrounding the ureter. In cases of extrinsic inflammatory change there may even be an easy plane of cleavage between the ureter and the lesion in the pelvis. Atonic dilatation is the mechanism by which the normal physiologic dilatation so frequently seen in pregnancy is produced. Recent experimental work by Traut, McLane and Kuder has shown that dilatation begins about the third month of pregnancy and continues to the seventh month, from then on it begins to recede and peristalsis gradually returns. I might also mention that this atonic dilatation is found in four-footed animals, namely, in mice and rats in which case the posture of the animal obviates the question of mechanical pressure. Obstruction by mechanical pressure may be produced by fibromyomas and ovarian cysts, although in the experience of Dr Cabot with whom I discussed this subject, it is not of so frequent occurrence as Drs Kretschmer and Kanter have pointed out. The most fixed point in the course of the ureter is at the crossing of the uterine artery. Fibromyomas arising in the lower third of the uterus and extending laterally generally pass either in front of or behind this point. If they pass behind this point the ureter may be dilated because of stretching over the tumor. Dilatation from inflammatory changes in the pelvis externally but intimately surrounding the ureter occurs as a result of interference with normal ureteral peristalsis. Surgical removal of such lesions in the pelvis as tubo-ovarian abscesses, inflammatory adhesions or fibromyomas allows the ureter to resume its normal peristalsis. Postoperative studies will show a return to a normal urinary tract in a high percentage of cases (about 95). All these patients should be investigated urologically in spite of or I might say because of their lack of symptoms so that urinary conditions which may influence the postoperative recovery may be discovered and taken into account in the care of the patient.

DR WILLIAM E. STEVENS, San Francisco. I found that about 824, or 9.9 per cent of the previous 8302 patients admitted to the women's clinic in the department of obstetrics and gynecology at Stanford University School of Medicine were referred to the female urology division because of urinary symptoms. These did not include patients with acute gonorrhea. Pathologic and physiologic changes in the generative organs, although present in a larger proportion were possible or probable etiologic factors in about 27 per cent of the 824 cases. The lesions of the genital organs which were most often responsible for associated urinary tract disorder were cervicitis, displacement of the uterus, tumors of the uterus, ovaries and broad ligament salpingitis and parametritis. The bladder and ureters are more frequently injured during gynecologic operations than the literature would indicate. One of San Francisco's best known gynecologists has recently been compelled to undergo a malpractice suit because of an alleged ureteral injury during a hysterectomy. The patient's urine was sterile. An abdominal tumor appeared on the sixteenth day. Examination by a competent urologist failed to disclose an injured ureter. More or less retention of urine usually follows major gynecologic surgery and residual urine may persist indefinitely. Pyelo-nephritis is a very common sequela. I do not believe that infection of the cervix is as frequently responsible for direct ascending lymphatic infection of the kidney as stated by several prominent observers. This may sound like heresy. Cervicitis ranked first among the lesions of the genital organs in our

cases but urethritis, trigonitis and cystitis were the most common urinary tract conditions with which it was associated. Displacement of the urethra is not infrequently associated with marked prolapse of the uterus and cystocele. Drs. Kretschmer and Kanter suggest the advisability of examination of the urinary tract in the presence of most genital lesions, although objective and subjective symptoms of pathologic conditions in the former organs may be absent. Conversely, examination of the genital tract in the presence of lesions of the urinary organs is often of great importance.

Dr. HERMAN L. KRITSCHMER, Chicago. There were two points that we tried to emphasize, one of them was the fact that the changes found in this group of cases occurred much more frequently than is generally supposed, especially in the group of patients who have no urinary symptoms and in whom the urine analysis is normal. The second point was that with the correction of the pelvic disorder, there was a rapid return to normal in a majority of cases at the time the patient left the hospital. In the small group of patients who still showed changes at the time of discharge from the hospital, subsequent check-up pyelograms showed a return to normal. The changes found in this group of cases are particularly identified with the changes found in the upper urinary tract in pregnancy. The patients who have urinary symptoms at the time they present themselves for gynecologic examination usually receive the benefit of a complete urologic study, so that when changes are present in the upper part of the urinary tract they are found. On the other hand the group of patients who do not have urinary symptoms receive no urologic study and hence lesions when present are naturally overlooked.

ROENTGEN DIAGNOSIS OF CONTUSIONS OF THE KIDNEY

MAX RITVO, M.D.
AND
DAVID B. STEARNS, M.D.
BOSTON

Injuries to the kidney have shown a great increase in frequency during recent years and are now of relatively common occurrence. Severe injuries are of the utmost importance because they constitute a serious menace to life itself, and these traumas have consequently received the consideration due them. Mild injuries to the kidney are more important to the practitioner in view of their greater frequency—traumas which may not at the time appear as significant but which may lead to the invalidism of chronic or recurrent infection and in some instances to subsequent formation of stone.

The diagnosis in severe cases is not difficult, the syndrome of pain, hematuria and prostration after a blow to the loin giving a characteristic clinical picture. With mild traumas, however, it has been impossible to determine with certainty whether or not damage to the kidney has actually taken place. Many injuries diagnosed in the past as contusions of the back muscles and lower ribs undoubtedly involved the kidney, the symptoms not having been of sufficient severity to point at the onset to renal damage. This type of trauma, with only moderate injury to the kidney, doubtless accounts for pain and lameness of the back which incapacitate the patient for an inordinate length of time. Indeed, signs and symptoms in cases of mild renal injuries are often so scanty that the diagnosis may be mentioned only as a possibility and cannot be made definitely by diagnostic methods previously available. The presence of blood in the urine has been considered the most

important sign of renal injury. Massive hematuria and prostration are absent in many instances, even microscopic evidence of bleeding may not be present with extra-renal oozing and edema. Also, many other causes of hematuria must be considered before one arrives at a definite diagnosis.

It has heretofore been generally recognized that the clinical manifestations of mild renal trauma are meager, variable and not definitely diagnostic. There may occur only transitory symptoms of variable duration, during which the patient complains of urgency and frequency, or, in some instances, there may be no urinary symptoms at the outset, with a deep-seated renal infection evidencing itself after the lapse of a few weeks. Roentgenologically, also, renal trauma has not been definitely demonstrable unless ruptures or tears of considerable degree existed, and then only if the damage communicated with the renal pelvis or calices. The

Fig. 1 (case 1)—Contusion of the right kidney. The left side is normal. On the right side the renal pelvis is flattened along its inferior surface and narrowed. The calices are compressed and elongated. The inferior calices are partially and the middle calyx is completely obliterated. The ureteropelvic junction is displaced upward. The right ureter is pushed medially in its upper and midportions.

present communication is concerned with a roentgenographic method of diagnosis in cases of mild or moderate injuries to the kidney and is applicable particularly to the type of cases which previously offered the greatest diagnostic difficulty, i.e., contusions of the kidney without severe tears or ruptures of the renal tissues. The observations on which this diagnosis rests were first made by one of us (D. B. S.) about one year ago. Since then we have observed a series of cases which form the basis of this report. This is the first note in the literature utilizing these signs in the diagnosis of renal contusions.

ETIOLOGY

Injuries to the kidney may result from a blow to the back, loin or abdomen and from indirect trauma such as a severe strain, a sudden bending of the body or a fall from a height in which one lands on the feet or the

buttocks. With the wider use of automobiles and the greater number of industrial accidents there will continue to be an increasing number of renal injuries. Some of the common causes of direct trauma may be enumerated as follows: falls from a tree porch or other point of elevation, football, basketball, hockey and other games entailing hard bodily contact, penetrating wounds due to sharp tools or knives and falls onto a picket fence, automobile accidents, industrial traumas, kicks from animals. The injuries are more common in men, owing to their greater exposure to these hazards.

PATHOLOGY

Injuries of the kidney vary from slight traumas to very severe rupturing or tearing wounds and may be classified according to the extent and location of the pathologic changes as follows: (1) edema of the renal or perirenal tissues, (2) extracapsular hemorrhage involving the perirenal fat and fascia, (3) tears of the capsule and perirenal tissues, (4) subcapsular tears

Fig. 2 (case 1)—Three weeks after figure 1. The changes on the right side are similar but distinctly less marked than previously, indicating improvement. The pelvis and calices remain distorted; the upper part of the ureter is displaced medially and its normal curves are still absent.

varying from single fissures to marked fragmentation (5) laceration of the parenchyma, capsule and perirenal tissues and (6) injuries to the pedicle, with rupture of the blood vessels or ureter or both.

The bleeding which results may consist of hematuria or intrarenal, perirenal or intraperitoneal hemorrhage. Edema occurs simultaneously in and about the kidney. Owing to the edema and the accumulation of oozing blood the calices and renal pelvis are compressed and the upper portion of the ureter is displaced medially and sometimes upward. These variations in the kidney pelvis, calices and ureter give the roentgen appearances characteristic of contusion of the kidney which are to be described in detail hereafter. As the fluid is absorbed, the changes gradually diminish and unless organization occurs within the perirenal tissues or kidney, the ureter and pelvis return to their normal position and contour after a few weeks. If fibrosis in the renal parenchyma takes place permanent alterations in the contour of the calices result.

ROENTGEN APPEARANCES

The roentgen examination is of the utmost importance in establishing the diagnosis of renal injuries and should be carried out in all cases unless contraindicated by the severity of the injury, in which instance it should be done as soon as possible. The first x-ray film may give helpful information occasionally and can often be made when the severity of the injury precludes more detailed studies. Some or all of the following signs may be demonstrable and assist the physician in arriving at a diagnosis: (1) haziness, or apparent enlargement of the renal shadow, (2) absence or blurring of the outline of the psoas muscle, (3) fixation or limitation of mobility of the kidney, (4) fracture of the lower ribs or transverse processes of the lumbar vertebrae and (5) scoliosis. It must be borne in mind that these signs may be associated with other conditions and are not pathognomonic of renal trauma.

Pyelographic studies are carried out by the retrograde or intravenous route depending on the condition of the patient. The retrograde method is usually the more satisfactory. Repeated examinations may be necessary and should be done as the patient's condition permits. With severe shock and hemorrhage, roentgen studies are contraindicated and should not be allowed to delay the prompt institution of proper remedial measures. A badly injured kidney may show very faint or no visualization on intravenous urography, the output on the unaffected side being normal. Extensive ruptures which communicate with the pelvis and calices are shown by extravasation of the opaque medium into the kidney parenchyma or subcapsular tissues.

In the past, the foregoing were the only recognized roentgen signs of renal trauma and required severe damage. However, we have observed definite x-ray appearances after mild or moderate injuries on the basis of which a diagnosis may be made. As has been mentioned a renal injury may result in edema and hemorrhage about the kidney, and in these cases we have observed characteristic changes in the ureter, renal pelvis and calices which are demonstrable on the pyelogram. The ureter normally courses downward along the margin of the lower pole of the kidney, then curves laterally for a short distance and in its middle third swings medially again, in cases of contusions of the kidney it is pushed toward the vertebral column forming an arc, and in some instances may even overlie the bodies of the vertebrae. The normal narrowings, dilatations and curves of the upper part of the ureter are obliterated, and this portion of the ureter becomes definitely pathologic in appearance. The ureteropelvic junction may be displaced upward. The kidney pelvis is narrowed and flattened along its inferior border, particularly if it is of the extrarenal type. The calices and infundibula become compressed and distorted, in some instances seeming almost spider-like. The ureter usually returns to its normal position in the lower lumbar or upper sacral region. Extravasation of the opaque medium into the kidney parenchyma or perirenal tissues may also be present if severe injury to the kidney has taken place, giving further indication of the extent of the trauma. Periodic re-examinations at intervals after the injury show the gradual return of the pelvis and ureter to normal position and contour, affording valuable information as to the absorption of the blood and edema and the healing of the renal injury. Therefore, the roentgen studies may have prognostic as well as diagnostic significance.

The demonstration of these changes in the renal pelvis, calices and ureter in conjunction with a history of trauma is positive evidence of contusion of the kidney. The absence of these appearances urographically however, does not exclude renal injury, as hemorrhage and edema may be so situated as not to produce them. As heretofore stated, no description of these roentgen appearances is reported in the literature, however on reviewing the prints of the roentgenograms published by various authors in discussions of renal injuries, we have found instances showing the changes described by us.

DIFFERENTIAL DIAGNOSIS

The following more important conditions must be considered in a differential diagnosis (1) renal neoplasm, (2) tuberculosis of the kidney (3) infections of the kidney and ureter and (4) perinephric abscess.

In cases of renal neoplasm, narrowing and irregularity of the renal pelvis and calices may occur and also varying degrees of distortion of the ureter. However, there is usually a history of loss of weight and strength with a mass in the kidney region, and reexaminations at intervals show progressive, destructive changes in the kidney. In cases of neoplasm, the hematuria continues to increase, while in cases of renal contusions the blood is usually small in amount and decreases with the passage of time.

Tuberculosis of the kidney may produce changes in the calices similar to those described by us, but the absence of flattening of the pelvis and displacement of the ureter together with the laboratory observations characteristic of tuberculosis exclude the possibility of contusion.

Infections of the kidney and ureter may cause blunting of the calices but do not present the changes in the renal pelvis and ureter which are seen after trauma.

In cases of perinephric abscess, arching of the ureter and flattening of the renal pelvis may occur, as with contusion of the kidney. However, there is an associated picture of sepsis which is absent in cases of renal contusion. The differential diagnosis may be difficult however, without a history.

REPORT OF CASES

CASE 1—J J W, a man, aged 26 was thrown from a horse and the horse fell on him bruising his right hip and loin. When brought to the hospital, he complained of pain in the right side, anorexia and weakness. Examination of the urine on admission showed albumin, rare red blood cells and a small amount of pus. Physical examination showed tenderness in the right lower quadrant and costovertebral angle.

Three weeks later he returned with nocturia, chills, malaise and continuous pain in the right loin. The temperature was 101 F and the pulse rate 120. Intravenous urography showed almost complete obliteration of the inferior calix on the right with medial displacement of the upper portion of the right ureter, consistent with edema and intracapsular and extracapsular hemorrhage.

Two days later the urine showed a specific gravity from 1.006 to 1.020, a slight possible trace of albumin, a few pus cells and in one specimen hyaline casts and red cells. The uric acid was 5 mg and the nonprotein nitrogen 48 mg per hundred cubic centimeters at that time, in the succeeding weeks the nonprotein nitrogen gradually dropped to 34 mg.

This patient presented definite evidence of edema and perirenal hemorrhage and had a typical case of contusion of the kidney.

CASE 2—W G F, a man aged 62 was injured in an automobile accident, being struck on the left side. Because of pain he was strapped, but without relief. He had urgency, urination every hour and nocturia (with urination three or

four times). The urine was darker than usual. There was no previous history of similar complaints. The urine showed a few white cells and otherwise nothing unusual. There was tenderness over the entire left part of the back and the left side, with a feeling of resistance in these regions. No mass was felt.

Ten days after the injury, pyelography was done. The catheter (no 5) met with obstruction at 8 cm. The middle and lower calices were narrowed; the upper ureter was displaced medially.

The diagnosis was contusion of the left kidney with renal and perirenal edema.

CASE 3—J F, a man aged 48 was tossed about severely in an automobile accident, landing on the back. Two days later he noted dysuria, urination every fifteen minutes and nocturia (with urination eight or ten times). There was no history of previous genito-urinary disturbance.

Eight days later there was tenderness over the left costovertebral angle, no masses were felt. The urine was clear, the specific gravity 1.010 and the reaction acid and there were rare pus and red cells.

Fig. 3 (case 2)—Contusion of the left kidney. The pelvis of the left kidney is small and flattened on its inferior surface; the calices are compressed and faintly visualized. The left ureter is pushed toward the midline in its upper and midportions.

Pyelo-ureterograms showed the right kidney normal. On the left the calices and pelvis were narrowed; the ureter showed displacement medially in its upper portion.

The diagnosis was contusion of the left kidney with renal and perirenal edema.

CASE 4—R B, a woman aged 34, was struck by an automobile suffering injuries to the back, abdomen, extremities and face. Twenty-four hours later she noticed frequency, urgency and nocturia (with urination about ten times) with pain in the left side. Two days later examination of the urine showed many white cells, a few red cells, no casts and a trace of albumin. The temperature was 99.4 F and the pulse rate 100. The patient remained in bed for several days and during that period continued to have urination every fifteen minutes, nocturia, dysuria, chills and pain in the back. There was also gross hematuria.

Two weeks after the trauma pyelography showed flattening and narrowing of the left renal pelvis with medial and upward displacement of the superior third of the ureter.

The diagnosis was contusion of the left kidney, perirenal edema on the left.

CASE 5—H A, a man aged 24 was struck by a truck, suffering multiple injuries, and was brought to the hospital unconscious. During his stay of eleven days in the hospital he had urgency, frequency and nocturia.

Two weeks later these complaints were still present. There was tenderness in the left side of the back and in the left flank and groin. The urine showed a trace of albumin, no casts and a few red and white cells. Pielography revealed compression of the left pelvis and calices with mesial and upward displacement of the proximal portion of the left ureter.

The diagnosis was contusion of the left kidney.

CASE 6—J M, a man aged 25, was struck while at work by an automobile and thrown to the ground being rendered unconscious. On admission to the hospital he complained of severe pain in the right upper quadrant and the right part of the back. There was no vomiting or hemoptysis. On examination there was tenderness in the right upper quadrant and over the right costovertebral angle. Spasticity and rebound tenderness were also present in the right upper quadrant.

Blood was oozing from the urethra, and the urine contained gross blood. The patient continued to pass bloody urine for several days. About one week after admission there was microscopic blood on urinalysis and this persisted for about eight days.

X-ray examination revealed a small narrowed renal pelvis with distortion of the calices on the right side, the upper and midportions of the right ureter were displaced slightly toward the midline.

CASE 7—W T, a man aged 41 fell a distance of several feet striking on his back. He complained of severe pain over the lower part of the abdomen and the back, especially in the region of the right kidney.

On examination there were tenderness and pain in the right lower quadrant and costovertebral angle, with moderate spasm. There were contusions and abrasions over the posterior aspect of the right side of the chest and midback.

Fig. 4 (case 4)—Contusion of the left kidney. There is fuzziness of the left inferior calices. The left renal pelvis is flattened and the ureter is displaced medially in its upper portion.

About six hours after the injury he passed bloody urine. The hematuria continued for four days. On the sixth day there were about twenty red blood cells per high power field, three days later microscopic examination revealed only a rare red corpuscle and a few white blood cells in the urine.

Pyelographic studies showed poor visualization of the calices on the right side, the renal pelvis was flattened, the upper part of the ureter was displaced medially and showed absence of its normal curves.

The diagnosis was contusion of the right kidney.

SUMMARY AND CONCLUSIONS

Injuries to the kidney have shown a great increase in frequency during recent years. The mild injuries have not in the past received the attention they merit.

In cases of severe trauma the clinical manifestations are characteristic, and diagnosis is usually not difficult. With mild or moderate injury, however, there has formerly been no satisfactory method of demonstrating whether or not actual damage to the kidney itself has taken place.

Fig. 5 (case 6)—Contusion of the right kidney. The right ureter curves medially and is displaced toward the midline. The right renal pelvis is compressed and the calices are distorted, particularly the inferior calices.

There is a roentgen method of diagnosis in cases of mild renal injuries, the type of case which previously offered diagnostic difficulty. Trauma to the kidney may cause edema and hemorrhage into and about the kidney. The extravasated fluid displaces the upper part of the ureter medially, narrows the calices and causes flattening of the inferior surface of the renal pelvis. These changes are demonstrable by pyelographic examination and give a graphic method of diagnosis in cases of contusion of the kidney.

ABSTRACT OF DISCUSSION

DR. EDWARD L. JENKINSON, Chicago: This paper offers a rather fertile field for further investigation. I should like to ask whether all the patients had blood in the urine and in the cases that did not show blood, whether they were of any consequence and whether or not further investigation is necessary. I should also like to ask how many of these cases show areas of calcification in the hemorrhages after this so-called rupture or injury to the kidney. Many of these observations are undoubtedly important but I wonder, in the absence of a history of injury, whether or not one could take one of these cases and from the displacement of the ureter or rather, the redundant ureter state definitely that the lesion was due to an injury. I believe there are a number of other conditions which undoubtedly would simulate a good many of these conditions.

DR. DAVID B. STEARNS, Boston: The authors have pointed out in detail the x-ray observations in contusion of the kidney. I wish to add a few words about the clinical picture about which

little is said in textbooks and the literature. In the cases I have had, the urinary symptoms have first been unnoticed by the physicians. Most cases of contusion of the kidney are regarded originally as simple back injuries. If the patient noticed frequency or urgency, he thought it might be due to nervousness. When this persisted, he decided that it might be of some importance and so brought it to the attention of his physician. Most patients have had pain in the loin. Frequency, urgency, nocturia and dysuria have been present in every case and started anywhere from six hours to forty-eight hours after the injury. In one fifth of the cases these symptoms were present for but three or four days. In the remainder they lasted from three to seven weeks. In 50 per cent a low grade fever was present beginning soon after the urinary symptoms began and in these cases the urinary symptoms seemed to last longer than in those cases in which there was no fever. Hematuria in various degrees was shown in almost every case. Two showed massive hematuria, so that the patient noticed a red or brown urine. Nearly all of them showed a number of pus cells in varying degrees when pus cells were present in large numbers, fever was usually also present and when there was fever and a larger number of pus cells the condition lasted longer. To rule out the possibility of urogenital infection in the older men a prostatic examination was made. In one case it was the finding of fever that turned the physician's attention from the simple contusion of the back to the possibility of renal injury. In two thirds of the cases in which the symptoms lasted for more than three weeks other laboratory examinations were instituted after examination to show the possibility of infection tumors or other conditions. Finally in one third of the cases urinary symptoms recurred showing evidence of lowered renal resistance one which occurred in five months and in another case twice during the following four years, which was the case of the first roentgenogram that was shown. Another point is the medicolegal aspect of this condition. The prognosis in contusion of the back muscles is quite different from that of the diagnosis of proved renal contusion in which there is a possibility of long standing renal infection and the possibility of precipitation of calculi may be present. In this series of cases, no calculus has as yet developed. Dr Squires in a recent paper reported a case of a motorcycle policeman who had fallen on his back but did not rupture the kidney. Bilateral calculi had been formed in his kidneys about three months after the injury. Calculus formation following kidney contusions therefore seems possible.

DR ROSS GOLDEN, New York. I should like to ask whether there is any contraindication to retrograde pyelography in these cases also what is the relative value of retrograde and intravenous methods of pyelography?

DR W. T. CLARK, Janesville, Wis. I should like to know how early the procedure was done in these cases. A few years ago I saw several ruptured kidneys which in the first day or two, showed a little blood in the urine. Two of those which came to autopsy were badly ruptured kidneys. The patients died quickly. To be of any particular use to those patients with regard to roentgen diagnosis, one must make that diagnosis relatively early.

DR MAX RITVO, Boston. With reference to the subsequent development of calcification this has not occurred in any of our cases. However it is a possibility, as we are familiar with post-traumatic calcification in hematomas and about the knee in Pellegrini's disease. Dr Ross Golden informs me that he has observed it in one case. Dr Jenkinson inquires whether the condition may be diagnosed without a previous history of injury. The x-ray appearances are diagnostic, although there are other conditions which may produce a somewhat similar picture. The situation is analogous to that in the diagnosis of silicosis. However, the roentgenologist is a medical consultant and should in every instance have a full knowledge of all the clinical facts that may assist him in arriving at a diagnosis. Although it is frequently possible to make a correct interpretation from the films alone, this is not desirable in order to perform his true function as a consultant, the roentgenologist should always know the history the results of the physical examination and other pertinent data. Dr Golden has asked whether there are any contraindications to retrograde

pyelography and the relative value of intravenous and retrograde studies. With reference to the first portion of the question the clinical aspects of the case are the deciding factors. If the injury was severe, as evidenced by shock and hemorrhage, retrograde studies are contraindicated with mild or moderate injuries, they may be carried out with safety. The intravenous route usually gives satisfactory results however we feel that retrograde studies are the method of choice in most instances. Dr Clark asks whether the examination may be carried out soon after the injury particularly in the case of a ruptured kidney. The present discussion has been limited to the milder kidney injuries. We do not advise the early use of this method of diagnosis in the very severe renal ruptures. After mild or moderate traumas, however we have carried out roentgen studies within a few hours of the time of injury, there have been no apparent ill effects in these cases and it is our belief that the examination is entirely safe if ordinary care is used in the selection of the cases.

MALUNITED COLLES' FRACTURES

WILLIS C. CAMPBELL, M.D.

MEMPHIS, TENN.

Malunion occurs more frequently following Colles' fractures than any other fracture. There is considerable disability, pain and deformity associated with this lesion, and the disfigurement is particularly unsightly in

Fig 1—Typical malunited Colles' fracture with posterior angulation of distal fragment and radial shortening.

women. My object in this discussion is to present a surgical procedure which accomplishes restoration of anatomic alignment and function and a wrist of which the appearance is practically normal.

Malunion of this fracture is most common for several reasons. First, failure to reduce the fracture completely. Second, recurrence of deformity after apparent reduction and confirmation by the roentgenogram. Third, excessive comminution with radial shortening. This occurs most frequently in elderly persons and rarely under the age of 45, owing to difference in structure of the bone. With the most efficient treatment, reduction may be accomplished but not always maintained, so that a certain percentage of malunion of moderate degree can be considered legitimate and excusable. This is particularly true if the articular surface of the radius is markedly comminuted. Fourth, complete rupture of the radio-ulnar ligaments with undue mobility of the lower extremity of the ulna.

Fifth, the possibility of a recurrence of the deformity if active motion and physical therapy are instituted at an early date, before consolidation is complete.

Malunion of sufficient degree to impair function in the wrist materially creates an unsightly cosmetic appearance which is well known. On examination the hand is at a grotesque angle to the forearm, owing to the radial shortening with the wrist in abduction, there is a dorsal prominence of the wrist if the backward

angulation has not been corrected with the head of the ulna protuberant laterally and anteriorly.

The wrist is usually wider than the normal particularly if the fragments were impacted or comminuted. Because of disuse there is usually considerable trophic change of the fingers with stiffness of the interphalangeal joints. Motion of the wrist is particularly limited in flexion and adduction with varying amounts of pain on motion.

Roentgenographic examination reveals the styloid process of the

Fig. 2.—Osteotomy of the radius three-fourths inch proximal to the articular surface.

radius at the level of the styloid of the ulna, or it may be even shorter, there is widening of the distal portion of the radius. The lateral view shows varying angulation of the articular surface from normal forward and downward tilt to marked backward displacement and angulation. In those above 40 there is often osteoporosis of the bones of the wrist and hand to a pathologic degree.

Owing to the marked variation as to the amount of bony deformity, differentiation must be made between the borderline cases which will respond to physical therapy with serviceable wrists and those in which surgery is expedient.

Two entirely different surgical principles are employed in malunited fractures: one restoring function by a compensatory procedure, the other by reconstituting normal anatomic relationships. By resection of a section of bone from the distal portion of the ulna some function may be restored, the logic of which is that the chief disability is due to limitation of rotation of the distal radio-ulnar articulation. This in no way restores the normal mechanics or contour of the wrist but is entirely compensatory.

A simple osteotomy of the radius may restore function of material degree and reduce the backward angulation but does not correct the abnormal contour of the radius and ulna.

The most efficient procedure is a plastic operation of the bone whereby the normal angle of the articular surface is restored, the radial shortening corrected and the prominence of the distal end of the ulna removed, thus reproducing normal external and bony contour. The technic of the operation is as follows:

A lateral incision is made over the lower extremity of the radius about 2 inches in length through the skin and superficial fascia between the brachioradialis and the abductor pollicis longus and the extensor pollicis brevis. By careful dissection the line of fracture is

exposed. A transverse osteotomy is made through the radius about three-fourths inch to an inch above the distal articular surface, after which correction of the posterior angulation of the lower fragment can be made by acute flexion of the wrist joint so that the lower fragment is angulated slightly downward and forward. In this position a hemostat can be inserted between the fragments and opened with moderate force, thus separating the fracture surfaces and demonstrating the amount of increase that can be obtained in the length of this bone. A skin clip is now placed so as to close this wound temporarily.

An incision is then made for about 2 inches over the medial aspect of the lower extremity of the ulna through the periosteum, which is stripped off of the inner half from above downward, exposing the articular surface and the styloid process. With a small osteotome the inner half or third of the head and inner portion of the shaft is severed from below upward, thus securing a free graft of bone about 1 inch in length and about one-half inch in thickness at one extremity and tapered at the other. This graft is placed in a covered sterile pan or sterile towel.

The free graft of bone is now trimmed with bone forceps to make a pyramidal wedge with a base on the dorsal as well as the lateral aspect, which is inserted into the space between the fragments. The dorsal wedge maintains the normal angle; the lateral wedge prevents recurrence of radial shortening. Care must be taken that there is slight overreduction of the lower fragment, that is, slight anterior angulation. Both wounds are then closed as a routine and dressed with small gauze pads. On inspection the external contour should be approximately normal except that the head of the ulna may not be prominent. The lateral dimension or width of the wrist joint should be normal and on palpation the lower extremity of the styloid process of the radius should be distal to that of the lower extremity of the ulna.

A sterile flannel bandage is placed from the metacarpophalangeal joints below to just above the elbow, and the sugar tong cast or molded plaster anterior and posterior splints are applied. While this is consolidating, the forearm is held in midposition the wrist in slight flexion, with pressure over the dorsum of the wrist so as to make the posterior capsule of the wrist joint tense, thus maintaining the lower fragment of the radius.

A roentgenogram is then made which should demonstrate practically normal anatomic alignment; the lateral view will show that the normal plane of the lower articular surface of the radius has been restored while the anteroposterior view will show that the styloid process of the radius is about one-half inch lower than the lower extremity of the ulna; the ulnar styloid process

Fig. 3.—Hemostat inserted between fragments to correct radial shortening; pyramidal wedge of bone removed from ulna.

having been excised. Roentgenograms should be made through the plaster splint at the end of one week and two weeks, in a routine manner, to determine position and thus adjust any slight recurrence of deformity. After one month the plaster splint is removed, roentgenograms are made and a small interior metal splint is applied with straps and buckles to allow frequent removal for active and passive exercises and physical therapy.

Fig. 4—Posterior angulation corrected by dorsal wedge of graft; radial length maintained by lateral wedge of graft; prominence of ulna removed.

The question naturally arises as to whether there is a probability of inducing delayed union or nonunion with recurrence of deformity or tenosynovitis from prolonged fixation. In answer to such a possibility, union in all cases has been accomplished in about the same time as in fresh fractures, though protection is continued for a period of eight weeks. As in other locations in the extremities of long bones in which an elongation has been accomplished by insertion of an autogenous graft such as the malunited fractures of the condyles of the tibia, union has not been delayed in a single case, nor has the graft undergone atrophy or sequestration but in all has healed and functioned.

END RESULTS

Surgical procedures have been carried out in forty-one cases of malunited Colles' fractures, twenty-two were simple osteotomies of the radius, nineteen were plastic procedures on the bone as described.

A reasonably high percentage of function was restored by osteotomy alone but the radial shortening and prominence of the ulna were not corrected. Thus except for correction of the angulation of the distal fragment little was accomplished toward normal anatomy.

The results from the plastic procedure on the bone have been uniformly excellent, meaning that contour is approximately normal and function restored to a material degree.

Of the nineteen cases eleven end results are excellent and seven are unknown. One case has not been entirely satisfactory, as there was excessive mobility of the lower extremity of the ulna due to ruptured interarticular fibrocartilage and it is too early to determine the amount of function that will be secured. Of the seven cases in which the result is not known, two were progressing satisfactorily when last seen so much so

that normal function could be predicted. The average age of the patients was 45 years with the oldest 66 and the youngest 29. The length of time from injury to operation varied from one month to one year, with an average of four and a half months.

The advantages of this procedure are that practically normal function is secured in a high percentage and an unsightly deformity is corrected which materially adds to the comfort of the patient.

869 Madison Avenue

ABSTRACT OF DISCUSSION

Dr. FRANK D. DICKSON, Kansas City, Mo.: Dr. Campbell has brought out that malunion of the Colles' fracture is a disabling condition particularly in industrial cases. The disability is the result of two things: first the incorrect alignment of the articular surface of the lower end of the radius and second shortening of the radius which brings about a disturbed relationship between the lower end of the radius and the ulna resulting in limitation of flexion and extension, limitation of abduction and adduction and limitation of pronation and supination. Another thing which I think he did not mention which is found frequently is the disturbing pain and discomfort about the lower end of the ulna resulting from its displacement and malalignment with the radius. All surgeons have been disappointed in the results of simple osteotomy in these cases; at least I have although the results secured by shortening the ulna to alter the malalignment between it and the radius have been fairly satisfactory. Such an operation, however, does not correct the disturbance of the lower articular surface of the radius. Dr. Campbell's operation seems very effectively to correct the malalignment between the radius and the ulna and also to restore the normal contour of the lower articular surface of the radius. I will certainly, in the future, give this procedure a very thorough tryout and shall hope to get the excellent results which Dr. Campbell has shown.

Fig. 5—Malunited Colles' fracture.

Dr. GEORGE E. BENNETT, Baltimore: I presume that a great many men in the audience have been utilizing bone grafts to fill in the space after an osteotomy has been done for the correction of a Colles' fracture. The technic which Dr. Campbell has described is certainly the one I am going to try the next time it is necessary for me to operate for the correction of this deformity. I have been taking grafts from the head of the tibia and placing them in the osteotomized area for many years, because if one does a simple osteotomy and brings the hand down in its corrected position a much longer healing period is required. In most cases I do an oblique osteotomy

of the ulna to correct the deformity. There is one point I should like to stress, which Dr. Campbell did not mention. Often patients with an old, malunited Colles fracture show a great deal of disturbance of the muscular and soft tissue of the hand, a fibrosis and an interference of circulation. In my early experience I operated in the presence of this condition at the end of, say, eight weeks doing an osteotomy and a correction, only to find that recovery was very slow. So for the past fifteen years I have made a practice of instituting physical therapy and getting the hand into the best condition possible before operation, thereby lessening the period of convalescence and securing better function of the hand. I think that if one attempts to do this operation before the soft tissues have reached their maximum recovery the results will not be as good as if sufficient physical therapy had been carried out before operation.

DR. DONALD C. DURMAN, Saginaw, Mich. For about ten years I have done an operation which is more simple but similar to the one described by Dr. Campbell. The operation and a small series of cases was reported in the *Journal of Bone and Joint Surgery* a year ago. I feel that it is worth

Fig. 6—Same case as in figure 5 three months after operation. Radial shortening and posterior angulation have been corrected and prominence of the ulna has been removed. Note function of pyramidal wedge.

mentioning here. An osteotomy through the fracture line is done on the dorsal surface, as described by Dr. Campbell. The ventral portion of the cortex is then fractured subperiosteally. Following this a graft of suitable length and breadth is cut longitudinally from the distal end of the upper fragment of the radius and is fitted transversely in the line of osteotomy. The graft holds the distal fragment in normal position. By making one end of the graft slightly broader than the other it is possible to correct the radial deviation of the hand. Resection of the distal end of the ulna has been found unnecessary to secure a good cosmetic result. After the graft is wedged into the line of osteotomy it is practically impossible to displace the lower fragment. In all my cases bony union has been well advanced at the end of three weeks. Two weeks after operation, plaster dressings are removed and replaced by an elastic bandage. All cases have had a very satisfactory functional and cosmetic result.

DR. WILLIS C. CAMPBELL, Memphis, Tenn. Some one has asked how I anchor the triangular ligament. That is usually done by suturing it to the adjacent periosteum or to the bone by means of a hole drilled through the ulna. As for the graft it is taken subperiosteally. I thoroughly agree with Dr. Bennett that these patients should not be operated on until after all acute symptoms have subsided and the structure is as near

normal as possible. If there is an extensive thickening or unusual edema of the hand which often occurs in elderly persons, I institute physical therapy as a preliminary measure. I suppose grafts have been taken from the tibia or the radius higher up, but it does not decrease the broadening of the wrist. The cosmetic results are of considerable importance particularly in women. I can see no reason why the extra incision should not be made and sufficient bone removed. The main point in this operation of course, is the elongation of the radius.

THE CARE OF THE FEET IN CHRONIC ARTHRITIS

JOHN G. KUHN'S, M.D.
BOSTON

The joints which are affected most frequently by chronic arthritis are those of the feet and the hands. Sometimes the disease subsides quickly but in most instances some permanent damage remains in these joints. More attention is usually given to rehabilitation of the hands, and adaptation in use is more readily obtained. Persistent disability of the feet however, is frequently observed. Normal activity and work are prevented by deformity, stiffness and pain. If the patient remains ambulatory, effective treatment is difficult and often impossible. Deformity and pain in the feet may increase after the arthritis is apparently quiescent as determined by both clinical and laboratory tests. Much, if not all, of the disability can be prevented by adequate early treatment. Deformities can often be corrected when the disease is quiescent, and a fairly close approach to normal walking may again be obtained. It is the purpose of this paper to outline the general measures which were found most helpful in restoring function in the feet of over 1,200 patients suffering from chronic arthritis who were treated for this special disability at the Robert Breck Brigham Hospital.

The deformities which develop in the feet do not differ greatly in the two great types of chronic arthritis, atrophic and hypertrophic arthritis. While there is usually greater pain and more rapid progression of deformity in atrophic arthritis, both types lead primarily to limitation of motion in the tarsal and phalangeal joints. The muscular weakness which accompanies this restriction of motion is, with weight bearing the chief factor in the progression of deformity.

Chronic arthritis in its early stages usually presents the same symptoms which are caused by chronic strain. Differentiation can usually be made from the history of progressive impairment of the general health, involvement of other joints and stiffness of the feet after rest which lessens with continued use. The swelling is variable in degree but more widespread and not limited to a special location (fig. 1). Limitation of motion in the midtarsal joints is one of the most common early symptoms.¹ The blood sedimentation index is elevated in most instances. Roentgenograms, which usually show nothing abnormal at the onset of the disease except swelling of the soft tissues, show progressive bony atrophy, clouding of the joint spaces and increasing narrowing and irregularity of the articular surfaces.

From the Robert Breck Brigham Hospital.
Read before the Section on Orthopedic Surgery at the Eighty Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 10, 1937.
1. Swaim, L. T. and Kuhn's, J. G. Prevention of Deformity in Chronic Arthritis, the Lower Extremity. J. A. M. A. 94: 1,43 (May 31) 1930.

These symptoms and these changes in the feet will be observed in about three fourths of all patients with early chronic arthritis. When they appear adequate treatment should be given, because subsequent deformity and lasting disability can be avoided. The only certain method of preventing future disability is to avoid weight bearing until the pain and swelling in the feet

Fig. 1—Early arthritis of the foot with generalized swelling about the ankle and spreading of the forefoot

subside. They usually do so rapidly, in a few days or several weeks. Heat in any form, but particularly in the form of hot foot baths, is helpful. If pain persists after the patient has been put to bed some method of immobilizing the foot should be employed. The simplest means is a well fitting plaster cast holding the foot in the normal weight bearing position. The posterior halves of such casts can be used only at night, when the patient has less pain. As pain and swelling subside exercises are begun to strengthen the muscles which support the foot.

Before the patient again becomes ambulatory, proper shoes and adequate support should be given to prevent strain. If this is not done a recurrence of the symptoms will usually be seen as soon as the patient begins to walk, and progression in deformity and extension of the arthritis will be observed. In general when arthritis is present, shoes should be sufficiently wide to avoid pinching the foot when weight is borne, they should have low, broad heels and firm, thick soles. Added support should be given if it is needed to maintain the normal weight bearing position of the foot. The foot should not roll inward, and a line continued downward from the mid patella should cross the foot at about the crotch between the first and second toes (fig 2). Added support for the foot is sometimes given by raising the front inner corner of the heel one-fourth inch, often a foot plate is necessary temporarily. Strapping of the foot where the skin will tolerate this procedure is a useful measure until muscular strength returns.

Exercises should be continued until the foot is strong. Strain on the feet cannot be permanently relieved unless the whole body is carried properly, for faulty weight thrust and muscular balance will be reflected in foot strain. Attention must be given to the posture of the whole body so that normal function of the muscles supporting the feet will be possible.

If inadequate treatment or no treatment is given and the arthritis remains, increasing deformity usually occurs. The deformity most commonly seen is one with the foot stiff in valgus (fig 3). In this position the irritated tarsal joints can be held rigidly by the muscles and motion at the ankle joint can be prevented. In walking however, it causes marked strain on the supporting ligaments of the foot and the strain is soon transmitted to the knee and the hip. When rigid valgus has developed, changes take place in the anterior part of the foot. Because weight bearing is faulty and because normal use of the intrinsic musculature of the foot is prevented, the muscles atrophy and a widening of the anterior part of the foot is seen, a flattening of the so-called anterior arch. This is followed by undue pressure on the heads of the metatarsal bones, and the symptoms are usually pain and tenderness. Pain may be referred along the digital nerves to the toes. If the shoes do not fit properly, the deformity progresses more rapidly.

When this degree of deformity has come, disability is severe, and the patient usually walks with great difficulty. The severe strains, which come chiefly on the foot and the knee aggravate the arthritis, and no subsidence of the inflammatory processes in the joints can be expected unless the deformity is corrected. Avoidance of weight bearing will bring temporary help, with a recurrence of symptoms when the foot is again used. Forceful correction of the rigid valgus may be necessary. This can be done most easily by the repeated application of adhesive plaster, a little greater correction of the deformity being secured with each application. In cases of more resistant deformities, a succession of plaster casts will sometimes bring correction. In the case of a very resistant foot, if the arthritis is quiescent, manipulation with the patient under anesthesia is indicated, followed by fixation of the foot in varus until the swelling and pain have subsided. When weight bearing is again undertaken adequate support of the foot is needed until normal strength has returned.

When weakening of the intrinsic muscles of the feet and spreading of the forepart of the foot persist, two other deformities develop hallux valgus and contracted

toe deformity. If there is much arthritic involvement of the metatarsal and phalangeal joints, these deformities develop much more rapidly. The hallux valgus follows the spread of the anterior part of the foot, owing to the faulty weight thrust in valgus, the pressure of the shoe and the pull of the adductors of the great toe, which have a greater mechanical advantage when the forefoot is spread. The deformity of the toes comes

Fig. 3—Rigid valgus with deformity of the great toe and dorsal contracture of the other toes.

from the depression of the heads of the metatarsal bones and from a more direct pull of the extensor tendons. This deformity of the proximal phalanx in dorsal extension is soon followed by subluxation of the proximal phalanx, usually lateral to the metatarsal head. With the osseous changes which accompany arthritis, marked deformation of the metatarsal heads and of the phalanges is seen (fig. 4).

Operative correction is not always necessary in the early stages of these deformities. Temporary cessation of weight bearing and exercises to develop the flexors of the toes and the intrinsic muscles of

the forefoot will help greatly. The chief concern is adequate support to the anterior part of the foot. This may be obtained by a foot plate which raises the forefoot medially to the second, third, and fourth metatarsal heads. Repeated plaster strapping and a leather cuff fitted about the foot just proximal to the first and fifth metatarsal heads are also useful measures.

When rigid deformity is present and the arthritis is inactive, a manipulation of the toes into flexion with the patient under anesthesia may be required. After the manipulation the toes can be held in plantar flexion by adhesive strapping for several days. Repeated manipulations will at times result in normal function of the toes. When subluxation of the proximal phalanx persists and there is marked deformity of the joint, the most rapid and usually the most satisfactory result is obtained by the operative removal of the distal half of the proximal phalanx. If the hallux valgus is severe, operative correction by removing the proximal portion of the first phalanx of the great toe usually gives the best functional result. Extensive reshaping of deformed bones has not proved a desirable procedure. After operation marked changes take place in the atrophied bones as the result of function. The simplest and least traumatic surgical procedure gives the best end result. Operative procedures are undertaken only when the arthritis is quiescent.

Ankylosis of the phalanges is not commonly seen. When it has occurred, removal of the entire proximal phalanx has given painless function without the subsequent development of calluses under the toes. This

operation has also been performed in cases of complete ankylosis of the first toe and the toe has become painless and useful. In cases of extreme deformity amputation of all the toes and occasionally removal of the heads of the metatarsal bones have been carried out. In no case have these procedures proved to be wise. A long foot plate has been required subsequently for the relief of pain. Calluses have developed under the forepart of the foot, since the rigid foot cannot adapt itself to the changed pressure of weight bearing. The functional disability has eventually become greater than before operation.

Hallux rigidus, with its limitation of dorsiflexion in the great toe, a deformity which develops not uncommonly in cases of hypertrophic arthritis, often produces great pain in walking. It can frequently be relieved by a long plate or by greater rigidity in the sole of the shoe. When these simple measures are not effective removal of the bony overgrowth on the dorsal surface of the metatarsal head will relieve the symptoms. Some times removal of the proximal third of the first phalanx of the great toe is necessary to permit painless motion in the first metatarsophalangeal joint.

One of the most disabling deformities is ankylosis of the tarsal-metatarsal joints. With this deformity there is loss of all flexibility in the forefoot. Usually the ankylosis is associated with a flattened anterior arch and flexion deformity of the toes. The metatarsal bones consequently become fixed in a position of increased plantar flexion. Calluses form rapidly, and pain is referred to the heads of the metatarsal bones. Occasionally the ankylosis can be broken by manipulation but usually an operation is required. The simplest procedure is removal of the proximal half inch of the metatarsal bone (fig. 5). This produces pseudarthrosis and permits movement of the metatarsal bone. When

Fig. 4—Roentgenographic appearance of chronic arthritis of the foot of four year duration. There are ankylosis of the tarsal joints and of the tar metatarsal joints and extreme deformities of the toe.

contracture has been present a long time this procedure may not be sufficient to permit motion of the distal end of the metatarsal bone. An osteotomy just proximal to the head of the metatarsal bone with the distal fragment held in a dorsiflexed position until healing has occurred will permit fairly good function but with severe contractures this procedure is usually not

as satisfactory as the removal of the head of the metatarsal bone. The head of the first or the fifth metatarsal bone should not be removed, since this disturbs seriously the balance and the weight bearing of the foot.

Ankylosis in the tarsal joints rarely yields to manipulation. If a fair weight bearing position of the foot cannot be secured with proper shoes and foot plates in operative correction of the deformity is indicated. The most useful procedure is a wedge osteotomy through the subastragalar joint or through the dorsum of the foot with the foot held subsequently in a good weight bearing position while the site of the osteotomy heals.

Spurs are frequently found in feet troubled by arthritis. They occur most commonly on the anterior plantar surface of the os calcis. They are also seen on the dorsal surface of the astragalus and tarsal scaphoid (fig 5). They are seen more often when there is no history or laboratory evidence of a gonorrheal infection than in the presence of such infection. We have come to feel that they are the result of chronic strain at points of ligamentous attachments. In the past ten years none have been removed by operation. When a proper weight bearing position of the foot has been obtained and the foot strain has been relieved the symptoms have disappeared in all but a few cases. In these temporary protection of the spur by a pad cut to surround it has given relief.

A disability constantly associated with arthritic involvement of the feet is epidermomycosis. The usual clammy condition of the skin, with impaired venous return, seems to offer an excellent medium for the growth of such infection. The infection yields readily to the usual remedies, but reinfection often occurs until the arthritis becomes quiescent and the circulation in the foot improves. When it has not been treated, healing of operative wounds has been markedly delayed.

Both local and systemic measures should be used to regain function in the foot crippled by arthritis. Treatment of the foot itself is inadequate, for disability will tend to recur unless the disease becomes quiescent. In treating deformities of the foot, one must appreciate the effect of contractures of the hip or the knee or of faulty posture on the function of the foot. An understanding of the disabilities which may arise in the feet and careful attention to preventing or correcting them will lessen greatly the permanent disabilities which follow chronic arthritis.

CONCLUSIONS

1 In chronic arthritis the feet are frequently attacked. They are often neglected in the treatment of the disease.

2 Deformities develop insidiously which can be prevented in the early stages by normal weight bearing and by proper support of the feet in walking until the disease is quiescent.

3 When there is extensive stiffness and pain, weight bearing should be avoided until the pain subsides.

4 With extensive deformity, operative procedures are often required. The simplest and least traumatic procedures to secure a good position for function will give the best result.

372 Marlborough Street

ABSTRACT OF DISCUSSION

Dr. LOUIS E. PAPURT, Cleveland: Dr. Kuhn has brought out that good body alignment and function especially of the knees and hips, are essential in the restoration of good function of the feet. Conversely, many an excellent work of reconstruction or preventive surgery of the knees and hips has been nullified by neglect of the feet. There are two points that I wish to add to the author's comprehensive outline. 1 Reports by Dr. Kuhn and his associates have indicated that at least 40 per cent of arthritic patients have intercurrent diseases. This means frequent periods of disability and bed rest. During these periods laxity and atrophy of the muscles and ligaments of the feet take place. A little preventive medicine in the form of heat and massage to the muscles plus active exercises to maintain muscle tone, and perhaps a soft arch prop as a temporary splint, will greatly lessen the post-illness disability and prevent recurrences of the deformities of the feet which may have taken so much time and effort to correct. 2 I have noticed in patients especially middle aged stout women, who have suffered from arthritis of the ankles and feet which may be quiescent, a hypertrophy of the fibro fatty tissue of the sinus tarsi or of the fat under either malleolus or even hypertrophy of the ankle synovia. These fat pads have been the seat of chronic passive congestion with fibrosis or actual inflammation and are often quite tender and painful. They tend to prolong the disability, and simple excision has given gratifying relief.

Dr. JOHN P. STUMI, New York: An exceedingly important point in Dr. Kuhn's paper is the early use of correct footwear to prevent deformities. If medical colleagues will give orthopedic surgeons the opportunity to treat patients at the onset of arthritis deformities can very frequently—almost always—be prevented. Furthermore when feet are just beginning to show arthritic changes, correct footwear and adequate rest will do much to control the inflammatory process and maintain strong weight bearing extremities. In arthritic feet with definite mid tarsal distortion associated with spasm or fibrosis, rigid foot plates have given me the best results. It was with hesitation that rigid foot plates were employed because of the fear that they would produce added discomfort in already painful feet. However, manipulation either with general anesthesia or with injection of the superficial peroneal nerve with procaine hydrochloride followed by immobilization, has been unsatisfactory. Best results have been obtained by personally making plaster of-paris impressions of the distorted feet having plates made to conform to these impressions without any effort at correction insisting that the plates be made of a metal malleable enough to be readily reshaped in my office, adjusting the plates at frequent intervals to obtain correction, and carrying out the adjustments in an exceedingly careful and gradual manner. By this treatment the static strain on the soft tissues and hence the discomfort has been relieved and the patients made ambulatory in the shortest time.

Medicine and Surgery Tend to Converge—And in all of this new visceral surgery it seems to me that the physician has merely come to do his own operating, that internal medicine is merely becoming surgicalized much as military surgery has become largely medicalized.

And what is happening in these specialties is an indication of the tendency in the two major branches, for internal medicine and surgery, as the treatment of disease grows less empirical unquestionably tend to converge.—Cushing Harvey, *Consecratio Medici* and Other Papers, Boston, Little Brown & Co, 1928.

FOOT DISORDERS IN GENERAL
PRACTICEDUDLEY J. MORTON, M.D.
NEW YORK

Only a small percentage of patients with a disorder of the foot reach the orthopedic surgeon, the rest—an overwhelming majority—are left unaided to seek relief wherever they can find it. For years they have been exploited so extensively by unqualified, nonprofessional agencies as to create a unique situation and one that has been accepted or condoned by the profession with extraordinary complacency. Why should these common ailments of the feet be so obviously the "ugly duckling" or "unwanted stepchild" of medicine?

At the beginning of this century, textbooks on orthopedic surgery suggested two primary causes of foot trouble, applying them to the disorder in the longitudinal arch and also in the metatarsal region of the foot, they were (1) badly designed footwear and (2) weakened musculature. After having received broad acceptance and approval for so long a period, it might be expected that these interpretations of primary factors would by now be well fortified with statistical and factual evidence, but such evidence is strangely lacking.

The original impairment of "faulty footwear" applied to shoes that were worn before the turn of the

proper. Since that time, however, and especially since the war, great improvements have been made both in the design and in the fitting of footwear. For men and children, shoes are now constructed closely along anatomic lines, and for women also conservative, well designed models are amply available. The high heel types are admittedly vicious, especially when worn continuously, they account chiefly for the far greater frequency of foot trouble in women than in men. But with this particular exception the severe criticism aimed at nineteenth century footwear does not have the same application today. Continuation of that criticism seems to be more a matter of habit than of reason, it has been fostered and sustained most loudly by the competitive claims of rival shoe merchants.

"Muscular weakness" has been given as the other primary cause of disorders of the foot. In the longitudinal arch the characteristic "weak ankle" or pronated posture of the foot is interpreted as due to weakness of the muscles on the inner side of the ankle and foot (the tibial muscles and long flexors of the toes), while in the metatarsal region "weakness of the muscles and ligaments" is vaguely referred to as permitting a falling or depression of an alleged "anterior transverse metatarsal arch."

Examinations of muscular strength in normal and pronated feet have shown individual differences in the comparative strengths of the supinators and pronators in the feet of all the persons examined, but these differences were so distributed among the normal and the pronated as to afford no significance whatever in their relation to abnormal posture.

The suggested "weakness of muscles and ligaments" in the forepart of the foot, permitting depression of an "anterior transverse metatarsal arch," is also vague at first, because there is no transverse arch formed by the heads (anterior ends) of the metatarsal bones as implied by that term and, second, from the standpoint of anatomy, there is neither a muscle nor a ligament in that part of the foot capable of sustaining such an arch if one were present.

Under thoughtful analysis, the given causes are not specific and concrete as basic factors should be in failing to supply an etiologic basis that clearly explains the mechanism of disorder they appear to be chiefly responsible for the lack of interest so generally shown

Fig. 1—A hypermobility of the first metatarsal segment is indicated by broadened line of lesser density between the cuneiform bones. Note enlargement of the shaft of the second metatarsal compared with the third, fourth and fifth. B shortness of the first metatarsal. Note the similar increased development of the shaft of the second metatarsal.

century and when they were designed and fitted with little consideration for the welfare of the foot. But even so, the injurious effects were limited chiefly to deformities of the toes and not to disorders of the foot.

by physicians. The studies presented here, reported in greater detail elsewhere,¹ disclose certain structural factors whose primary disturbing influence on the function of the foot is plainly demonstrable. They are described here because through accurate knowledge of primary causes general practitioners, as a group, can become the most important and effective agency in controlling the extensive incidence of disorders of the foot and in establishing a normal professional relationship with the public in this avoided field.

NORMAL PHYSIOLOGY

Studies in the past have been made chiefly from observations of the foot as a composite unit and in terms of total function, so that the values of integral parts have escaped due consideration. The importance of the latter phase in the analysis of any composite structure becomes obvious when it is recalled how the total power output of an engine can be seriously affected by the maladjustment of some minor part or how the volume and tonal qualities of a radio can be ruined by defect in a single unit. In such instances, only through familiarity with what each part of the structure should perform can a person knowingly locate and correct the trouble. Such an analysis of segmental values has been employed as the basis of the present investigations, and a physiologic, rather than a morphologic, approach has been followed.

Human feet are designed for two extreme types of function, they serve (1) as a stable base for standing erect—a relatively passive act because it calls for a minimum of dynamic (muscular) action—and (2) as levers in forceful locomotion (running and jumping) in which the dynamic action of the muscles strongly predominates. Walking, an intermediate type of function, includes modified phases from both of the extreme types of function.

In stance, half of the body weight is transmitted by the leg bones on each foot, where it is divided, a part passing backward to the ground through the heel, the rest being carried forward and distributed among the five metatarsal bones for transmission to the ground. It is important to distinguish this weight bearing function of the foot proper from the purely accessory action of the toes, because the latter are not involved in the actual support of body weight. This is easily demonstrated, for when a person stands erect he can lift his toes from the floor without any shift in the body's center of gravity. If he bends forward or intentionally shifts his weight in that direction, contraction of the flexor muscles pulls the toes into firm contact with the floor, thereby adding their length to the anterior stabilizing property of the foot. Body weight, however, is still being borne essentially by the metatarsal bones.

With the framework² of the foot thus recognized as the prime weight supporting structure, its elements of stability should be identified. It is triangular as viewed from above. The heel, representing the posterior corner of the triangle and being a single point of contact, is of itself without stability in any direction. The added contact of the forepart of the foot to the ground is necessary for anteroposterior stability, and its width through the spread of the metatarsal bones furnishes the necessary elements for stability in lateral directions.

A staticometer was designed to learn what each weight supporting segment contributed to the support of body weight and to the structural stability of the foot. The tests showed that, in normal stance, weight stresses are divided equally between the heel and the forepart of the foot, and, of basic importance to subsequent studies of foot disorder, it was found that the forward stresses were normally distributed on metatarsals 1 to 5 in the approximate ratio of 2, 1, 1, 1, 1 respectively. Since the sesamoid bones beneath the head of the first metatarsal serve as two points of contact for that bone, six points of ground contact are to be recognized in the forepart of the foot with each transmitting an equal share of body weight (fig 3a).

Thus in a person of 120 pounds (54 Kg) the distribution of weight in stance is as follows. To each foot, 60 pounds (27 Kg), to the heel, 30 pounds (13.6 Kg), to the first metatarsal, 10 pounds, or 4.5 Kg, (each sesamoid 5 pounds, or 2.3 Kg), to the second, third, fourth and fifth metatarsal, 5 pounds to each. These tests help to identify the foot not as a single arched

Fig. 3—*a* a normal ratio of weight distribution (2 1 1 1 1) indicated by equal sized squares. *BB* vertical plane of balance. *IB* and *BV* equal medial and lateral margins of structural stability. *b* first degree pronation. unit but as a series of five separate longitudinal arches united posteriorly in the heel. In these arches the adjustment of the plantar ligaments to the front segments is so accurate that in gaining supporting contact on a level surface the metatarsal bone of each longitudinal span receives only its apportioned share of the total load. Also, by locating between the second and third metatarsals an even division of stresses imposed on the forepart of the foot, one is able to identify an axis, or plane of balance, as passing through this point and through the centers of the ankle and heel. The width of metatarsal contact with the ground on each side of that axis (*IB* and *BV*) represents the equal margins of structural security that characterizes the foot in normal posture.

Standing involves continuous static strain for periods of greater or less duration. This is a type of strain which ligamentous tissue is specifically designed to withstand. Also it may here be noted that both to the rear and forward the static stresses are divided through the framework of the foot in close accordance with the pro-

1 Morton D J. The Human Foot. New York: Columbia University Press, 1935.

2 The term framework includes the bones and also the ligaments for like rivets in the steel framework of a building the ligaments are the essential binding elements that maintain the supporting units in position.

portionate stoutness of the six supporting segments, namely, the heel, the first metatarsal and the four lateral metatarsal bones

Forceful locomotion, the opposite extreme in function, presents quite different physiologic features from stance. When propelling force is applied on the heel by the calf muscles (*gastrocnemius* and *soleus*), body weight is levered forward along a second, or leverage, axis of the foot.³ This axis differs from the axis of balance in that it passes between the first and second metatarsals instead of the second and third. In the ideally designed human foot the heads of the first and second metatarsals are equidistant from the heel, so that when the heel is raised in locomotion the heads of these two bones act together as the fulcrum of leverage (fig 4A). The movement is helped by the bowstring action of the muscles located on each side of the ankle behind the malleoli, while at the same time these muscles act as sides of a trough to keep the movement balanced on the leverage axis.

Fig. 4.—A axis of leverage indicated by the long arrow. The first and second metatarsals share the leverage stresses. B a short first metatarsal causes leverage stresses to be concentrated on the second metatarsal alone. Also see figure 5B.

In locomotion the weight stresses are thrown entirely on the fore part of the foot through two bony channels. The lateral stream passes toward the cuboid bone, where it is deflected medially by the peroneal muscles and by the three lateral metatarsal bones which act as auxiliary levers. In order to counterbalance the outward movement of the lateral stream, the medial stream is at first directed somewhat inward in conformity with the mild medial deviation of the neck of the talus. It is then swung more forwardly and laterad by the muscles acting on the inner border of the foot (*tibials* and *long flexors* of the digits). The two streams now converge on the two inner cuneiform bones and the bases of the first and second metatarsals, whence they are transmitted to the ground. Thus in forced locomotion the stresses are balanced on the axis of leverage, and the heads of the first and second metatarsals act together as the fulcrum.

³ Studies in the evolutionary development of human feet have shown that this leverage axis is a prehuman feature and that the longitudinal arch has been formed in direct relation to it. The axis of balance is a later acquisition attained only as the inner border became permanently arched.

In walking, the movement of these stresses is modified. In the early half of the foot's contact with the ground they are centered on the axis of balance and then swung toward the fulcrum.

In contrast to the continuous and milder static strains of stance, forceful locomotion introduces brief and violent strains and stresses, which converge on the forward inner corner of the triangular human foot, i. e., on the first and second metatarsals. The violence and concentration of these stresses would put a tearing strain on the plantar ligaments of these two medial segments were the excessive burden not absorbed by the posterior tibial and long flexor muscles. These muscles enter the foot in the vault of the longitudinal arch and therefore are located ideally to sustain the arched segments against the crushing force. The first metatarsal segment, in particular, is well protected by the flexor hallucis longus, the course of which runs immediately beneath it, while the intrinsic muscles within the foot also contribute directly to absorption of these concentrated stresses.

LIGAMENT VERSUS MUSCLE FUNCTION

In view of the widely held concept that the muscles are the chief means of supporting the longitudinal arch, it seems fitting to point out how specifically and differently the requirements of stance and locomotion concur with the distinctive functional qualities of ligaments and of muscles. Just as ligaments are uniquely adapted for the continuous and prolonged strain of static stresses in stance, so the brief, intermittent and violent stresses of locomotion are directly in accord with the known physiologic properties of muscle tissue. Such individual spheres of action indicate that the muscles are not employed to sustain the arch but that their function in stance is merely to hold the leg bones vertical on the foot by means of a light tonal tension. For example, the relaxation of the muscles in a fainting person does not alter the contour of the foot but it eliminates normal control of the leg bones in their position above the foot. In other words, the muscles on the two sides of the ankle act on the leg as stays on the mast of a ship, the purpose of the stays is to maintain the mast in proper relation to the ship's hull and not to pull the hull into a correct position beneath the mast. In both instances the foot and the hull are the stable basic structures while the leg bones and the mast are the mobile elements. Only a light tonal effort is normally required of the muscles to balance the leg bones in stance on a stable foot, but a strongly sustained contraction, as implied in direct support of the arch under body weight, is entirely incompatible with our knowledge of muscle physiology. It may therefore be concluded that, so far as the arch is concerned, stance calls only for ligamentous function while locomotion utilizes both ligamentous security and muscular protection and activity.

DISORDERS OF THE FOOT

Physiology indicates that intrinsic as well as extrinsic factors are to be considered in foot trouble. Leg muscles and shoes represent extrinsic factors because they are outside the foot itself. In contrast, intrinsic factors are those which, being located within the foot, affect its internal mechanism directly.

The heel is conspicuous in its size and in the importance of its functional role both in stance and in locomotion, but the postural security of the heel as well as of the entire foot is directly dependent on the radiating spread of the more lightly built metatarsal segments which gives the foot its breadth. Consequently the fore-

part of the foot is the prime factor in foot posture, and of its five segments the first metatarsal segment has been shown to be of greatest functional importance. In stance it is the essential stabilizing member on the medial side of the foot and normally supports twice the load carried by each of the others, in locomotion it alone with its associated muscles sustains half of the greatly intensified stresses imposed on the foot. Thus the first metatarsal segment is marked as so vital a unit to the mechanics of foot function that any defect or deficiency in it would impair the foot's entire mechanism. Also, because of its corner position in the foot's triangular framework the disturbance would involve to a greater or less degree both the arched inner border and the front border.

The two most common external signs of foot disorder are (1) a pronated, unbalanced posture and (2) callus formation on the sole of the foot, behind the second and third toes. Pronation occurs usually as "weak ankles" early in child life. Its long recognized association with trouble in the longitudinal arch has not only made it the best known sign of foot disorder but has established it also as a morphologic index by which the degree of trouble is estimated. Callus formation in the area designated is likewise typical of foot disorder but, since it does not develop as a rule until after physical maturity (25 years or more) has been attained, its significance is not so generally recognized.

Both of these signs point directly to a functional deficiency in the first metatarsal segment. Whenever such a deficiency exists, the stresses which this segment should normally carry are shifted and concentrated on the adjacent second. This phenomenon is consistently associated with hypertrophy of the shaft of the second metatarsal bone. Physiologic tests confirm this interpretation.

Two structural conditions have been identified which are directly responsible for the impaired functional qualities of the first metatarsal segment. They are (1) laxity of its plantar ligaments, allowing a dorsal hypermobility which prevents the first metatarsal from attaining firm supporting contact with the ground at the same time as the others (figs 1A and 5A) and (2) shortness of the first metatarsal bone, whereby the more advanced head of the second metatarsal must serve alone as the fulcrum of the foot's leverage action (figs 1B and 5B).

Dorsal Hypermobility (fig 1A)—Laxity of ligaments in the first metatarsal segment affects both distribution of weight and postural security. The double burden it normally supports in stance falls on the second metatarsal in the same way as when five men are carrying a heavy log and the man on one end lets go his hold—his share falls immediately on the man next to him. Also, through the relative noncontact of the first metatarsal, the medial margin of structural security is primarily reduced to the short distance between the normal axis of balance and the head of the second metatarsal.

The overloading of this more slenderly built bone causes its ligaments to be strained and stretched, and the foot pronates or rolls medially. If the hypermobility of the first metatarsal segment is slight, ground contact is quickly gained and the movement is arrested, but with the following modifications in function which characterize what may be designated first degree pronation (fig 3b). The vertical plane through the center of the ankle joint is now shifted between the first and second metatarsals. There is also a medial shift in weight

from the outer border of the foot, so that weight distribution has been changed to the approximate ratio of 1, 2, 1.5, 1, 0.5. Static stresses are still concentrated on the second metatarsal, but the first metatarsal has reassumed some weight bearing function, and its width now alone comprises the reduced margin of structural stability. Such feet are not appreciably impaired for the active function of locomotion (in fact, they are commonly seen among athletes), but they tire more easily under prolonged standing than feet with normal posture.

Where greater laxity in the plantar ligaments of the first metatarsal segment exists, pronation must proceed further before that segment acquires effective ground contact. Second degree pronation may therefore be considered the stage in which the center of transmitted weight on the ankle has moved medially until the vertical plane (passing through it and the central point of heel contact) projects forward through the head of the first metatarsal bone. The medial margin of structural stability is now eliminated, and only the muscles and the ligaments on the inner side of the ankle and foot remain to prevent greater unbalance in posture. Until

Fig 5—A a kinetograph print of the foot with dorsal hypermobility of the first metatarsal segment (fig 1A) showing concentration of leverage stresses on the second and third metatarsals in walking. B a similar kinetograph print of the foot with a short first metatarsal (fig 1B) showing concentration of stresses on the second metatarsal only.

contact of the first metatarsal with the ground is gained, weight distribution is increasingly disordered to a ratio approaching 0, 3, 2, 1, 0 (fig 1A). The exaggerated load on the second and third metatarsals introduces two sources of symptoms: cumulative strain of their basal joints, causing a local traumatic arthritis (usually subacute), and callus formation from intensive pressure on the skin beneath these metatarsal heads.

Such feet are definitely predisposed to joint and muscular strain both in stance and in locomotion. When standing is of more than brief duration, the lack of medial security allows the unbalanced posture to increase and, in order to prevent it, the muscles are kept in a constant state of hypertonic tension, they tire and yield, with the result that the unrelenting static stresses fall even more heavily on them. Eventually only the ligaments of the inner side of the ankle and foot remain effective to obstruct further unbalance and deformity.

The mechanical elements of locomotion are thrown out of order correspondingly. The pronated posture alters the position of the joint surface beneath the talus, depressing its inner margin (*sustentaculum tali*). Consequently body weight becomes deflected more and more heavily on the medial border of the foot and against the muscles on that side of the ankle. These muscles

must resist and redirect this exaggerated load back on the foot and on the metatarsal heads as the fulcrum. However, persons with second degree pronation may never manifest subjective symptoms if they lead sedentary lives and avoid physical activities in excess of the reduced capabilities of their feet.

The evidence indicates very clearly that the muscles are not primarily at fault in disorders of the longitudinal arch, on the contrary, it signifies that pronation is caused by lack of structural stability in the medial segment of the foot's framework and as a result the muscles suffer secondarily from abnormal overloading.

Third degree pronation, applied to more conspicuous cases of deformity, presents two distinct types, the rigid and the flexible flatfoot, with widely different ranges of clinical symptoms. Of course, all intermediate degrees between these two types are to be observed, as well as in the stages of advance from the milder to the more extreme degrees of deformity.

The rigid flatfoot results from progressive deformity and inflammatory changes begun usually at the stage of second degree pronation and exaggerated by continued

the critical stage. It covers the great majority of cases that present clinical symptoms. At this stage and prior to it, physicians have their greatest opportunity to employ corrective and preventive help with maximum success.

Shortness of the First Metatarsal Bone (fig 1B)—This factor impairs the effectiveness of the first metatarsal segment chiefly in locomotion, because the more advanced position of the head of the second metatarsal causes the latter to act alone as the fulcrum of the foot's leverage (figs 4B and 5B). When the heel is raised in locomotor effort, all the stresses must converge on, and be transmitted by, this more slender bone. The condition is an inherited one and its presence from birth causes the shaft of the second metatarsal to become increasingly hypertrophied throughout the physically active periods of life. The widening of its shaft results apparently from the convergence and crossing of the two streams of locomotor stresses, the thickening of the walls (cortex) seems due more directly to the exaggerated vertical stresses.

A short first metatarsal bone affects chiefly the basal joints of the second metatarsal segment by reason of the intensified breaking strains imposed on the latter's plantar ligaments. These strains, acting as repeated injury, produce a local inflammatory reaction of the metatarsal joints, which becomes gradually an actual traumatic arthritis, accompanied at times by an effusion tending to separate the bones. When this occurs, the normally close approximation of these bones is lost and minor movements are permitted which are highly irritating to the adjacent nerves (Morton's metatarsalgia⁴).

A short first metatarsal bone forms a very unfavorable combination with the high heeled shoes of women. Such shoes hold the foot at midpoint in the arc of leverage action, so that both in stance and in locomotion the second metatarsal bone is constantly subjected to a severe overloading of weight stresses.

Of similar effect as shortness of the first metatarsal, a third factor has been identified in a rearward position of the two small sesamoid bones that normally underlie the head of that bone. Since these sesamoids represent the contact points of the first metatarsal with the ground, whenever they are located more proximally toward the neck of that bone and posterior to the head of the second metatarsal they create a potential shortness of the former and affect the mechanism of the foot accordingly.

SYMPTOMS AND DIAGNOSIS

Functional deficiency of the first metatarsal segment furnishes a basis on which the widely diversified range of symptoms in foot disorders are easily interpreted and understood. The three structural factors identified may exist singly, but usually they occur in combination (fig 2). In either case their effect on the foot's mechanism is consistent and positive. They are to be regarded as primary causes because they directly reduce the functional capabilities of the feet. However, in order for clinical symptoms to appear, their presence must be supplemented by abusive function—abusive, not from the point of view of what normal feet can stand but because it is excessive to the subnormal capabilities of these feet. The abusive elements are of two major classes: (1) unfavorable conditions of function, which apply to environmental or personal factors, such as hard floors, city pavements, high heeled shoes and ill health, and (2) excessive degrees of function, such as long

Fig 6—*a* a more advanced degree of dorsal hypermobility. *DH* lack of ground contact. Increasing pronation (indicated by arrows) with greater disorder in the distribution of weight. Note complete loss of the medial margin of structural stability. *b* use of compensating platform (*CP*) to correct distribution of weight and restore the medial margin of stability.

disordered function. Secondary faulty stresses are created which impose uneven and distorting pressures on joint surfaces and abnormal strains on ligaments. Alterations in the bones lead to a permanent loss of the arch. Arthritic and neuritic changes of a more lasting nature are established under the functional trauma. Vasomotor symptoms appear as a part of the nerve involvement. The advancing deformity causes further changes in weight distribution, the first metatarsal is forced to the ground more strongly and its load is steadily augmented as weight is shifted medially from the outer border of the foot.

Flexible flatfoot, as the other type, is traceable to an unusual degree of ligamentous laxity in early childhood, or congenitally. In these cases subjective symptoms are comparatively negligible but the deformity is conspicuous. Such feet are distinguished from normal but very low arched feet by their marked pronation, their greatly reduced functional capabilities and the typical flatfoot gait.

The progressive course of longitudinal arch disorder as discussed clearly stamps second degree pronation as

⁴ First described by Prof. T. G. Morton in 1876.

hours of work on the feet, violent sports and obesity. After subjective symptoms have once been established, another factor—traumatic inflammatory changes—has been added and must be reckoned with in the explanation of symptoms as well as in the scheme of treatment.

Symptoms are traceable to two primary sources: (1) uneven distribution of weight on the metatarsal bones with stresses concentrated chiefly on the second, and (2) loss of structural stability on the medial side of the foot.

Uneven distribution of weight is associated with all three of the structural factors. It is responsible for superficial and deep symptoms. The superficial symptoms are caused by excessive skin pressure and usually start as a burning sensation in the sole of the feet, later followed by callus formation under the middle metatarsal heads (especially the second). This callus may become thick enough to act as a foreign body and be an added mechanical source of local pain. Deeply, the strain of the basal joints sets up a traumatic arthritis, which in the more acute cases presents a characteristic area of deep tenderness (fig 7). Because of its close proximity to these joints, irritability or inflammatory involvement of the medial plantar nerve with the fanlike distribution of its branches accounts for the various types of metatarsalgic pain in disorders of the foot. The second source of symptoms, loss of medial stability, is more commonly caused by dorsal hypermobility than by shortness of the first metatarsal. Pronation muscle exhaustion and spasm, and pain from strained ligaments along the inner border and arch of the foot are its more characteristic symptoms.

All the foregoing symptoms may be regarded as primary because they are directly allied with the original phases of disorder. However, after the establishment of the inflammatory condition, symptoms and changes of a secondary nature make their appearance. The signs of nerve involvement predominate subjectively and increasing deformity objectively. Pain is extended up the legs and thighs to the back, while in the feet local areas of numbness, tingling or sharp pain develop. Vasomotor disturbances appear also, the feet perspire profusely, they may become discolored or mottled in appearance, and swelling may occur in the feet and ankles. In advanced cases of disorder of the longitudinal arch, the tarsal bones become altered in shape because of uneven, distorting contacts, and the foot is gradually depressed into fixed and rigid flatfoot deformity. In metatarsalgic cases progressive claw toe deformity is the more characteristic change.

The most valuable and accurate means of diagnosis is the dorsoplantar x-ray film of the foot with the x-rays centered on the middle cuneiform bone. Although x-ray examinations are rarely used in these cases, the evidence that they disclose of faulty function gives them the same relation to foot disorders as cultures to bacteriologic diseases.

The first feature to receive attention in the film is the presence and the degree of enlargement of the second metatarsal in comparison with the three outer metatarsal bones, because it is a definite index of abnormal distribution of functional stresses. Width of the shafts and thickness of cortex must be considered in the comparison, also age, as such hypertrophy is less developed in younger than in older persons.

Shortness of the first metatarsal, actual or potential, is identified by the position of its head and of its sesamoids in relation to the head of the second metatarsal (figs 1 B and 2).

Dorsal hypermobility of the first metatarsal segment is indicated in the x-ray film by a broadened line of lesser density extending backward between the medial and the middle cuneiform bone from the first intermetatarsal space (figs 1 A and 2).

A lateral x-ray view of the foot is desirable to complete examination data and is especially helpful in differential diagnosis.

Shortened Calf Muscles—There is one extrinsic condition which may be either an important direct or a contributing factor in functional disorders of the foot. It is a shortening of the calf muscles (gastrocnemius and soleus) which reduces the normal range of dorsiflexion of the foot. Although most commonly acquired by women through constant use of high heeled shoes, it is sometimes congenital or may develop during a protracted period of illness in bed, unless care is observed toward its prevention. In the cases caused by the use of high heels, symptoms of foot trouble usually follow an abrupt change to very low or flat heels, the feet are strained and forced into pronation by the crushing leverage of the legs on the arch under the momentum of locomotion. The mechanism of disorder differs from that of a hypermobile first metatarsal segment in that the concentration of stresses falls directly on the first metatarsal instead of on the second. After any long illness, weakness of the ligaments is an additional factor in this type of foot trouble.

Fig 7—Characteristic point of deep tenderness in the sole indicated by shaded circle. Observe the immediate proximity of the medial plantar nerve and distribution of its branches.

TREATMENT

Ordinary disorders of the foot are not difficult to treat and respond readily to a thoughtful and methodical plan of procedure. The important objective to be borne in mind is first to restore a painless condition and then to establish improved conditions of function. This demands equal attention to three clearly defined sources of pain and disability, namely, (1) superficial irritation, (2) deep trauma and inflammatory changes, and (3) disordered mechanics.

1 Superficial Irritation—The first step in treatment applies to all surface elements of discomfort. Painful calluses, corns, warts or other skin growths should be regarded as foreign bodies. Their immediate removal or treatment is indicated just as positively as a pebble in the shoe or a cinder in a person's eye. Patients will not recognize success in treatment of foot disorders as long as they continue to experience discomfort from these superficial sources. The manner of treating them, whether through the services of a chiropodist or by means of x-rays, radium, electricity or chemical preparations, is best determined by the nature of the growth. After their removal, the area should be protected with adhesive tape or moleskin for a period of a month or six weeks.

It is equally necessary to check immediately on the style and fitting of the shoes, especially the shoes that are worn during working hours. A conservative, conventional model is recommended for which no claims are made other than that it is an article of apparel,

just as a hat or a glove. Proper fitting should provide ample length and toe space. A straight inner border is not desirable if it gives too much room to the great toe and cramps all the smaller ones. The heel fit should be snug, and there should be sufficient metatarsal width both in the upper and in the sole. In women's models it is not uncommon for the sole to be cut so narrow that the head of the fifth metatarsal overhangs the edge instead of being supported on the flat surface of the sole. Also a light metal reinforcement is a desirable feature in the narrow shank of women's shoes. This reinforcement is not an arch support but a useful stabilizing element between the high and narrow heel in back and the front portion of the shoe.

In general, the shoe should be a protective, physiologic foot covering, thoroughly comfortable and reasonably gratifying to the esthetic sense of the patient. Greater liberty may be granted toward shoes used for dress occasions, because then the feet are not usually subjected to the same degree of functional strains. A little discretion in selecting shoes according to occasion will do much to prevent, as well as cure, painful foot trouble in women.

2 Deep Trauma and Inflammatory Changes—One of the most important factors toward successful treatment is a clear realization of the irritated state of the deeper tissues and their need for specific care. Too frequently an immediate cure is expected from the mere application of some mechanical device to the foot or shoe. The presence of subjective symptoms leaves no question as to the traumatized state of the tissues beneath the surface of the foot, and it is equally obvious that function is the traumatizing agent. Sick people are put to bed, strained joints in other parts of the body are immobilized and treated locally, but strained feet are expected to get well while they continue their usual daily labors. Thus it is not always easy to obtain full cooperation of the patient.

Emphasis must be placed on the fact, therefore, that all reasonable restriction of physical activities is imperative during the painful period. In addition, a brief interval of reclining or sitting with the feet elevated to hip height should be arranged for the morning and afternoon, in order to minimize the cumulative irritation of continued function.

Circulatory stimulation is the most effectual means of combating muscular exhaustion, trauma of the tissues and inflammation, and also the various forms of nerve and vasomotor disturbance. Different forms of physical therapy are used for this purpose, but contrast plunges deserve special mention because of their high degree of effectiveness while entailing little or no expense to the patient. They are taken in two buckets with the water of sufficient depth to submerge the feet and legs at least 6 inches above the ankles. The timing is important.

The feet are plunged first into the hot water as hot as can be borne comfortably for one and one-half minutes and then immediately into the cold water for one-half minute. After repeating the process five times, the feet are dried by a brisk rub with a rough towel. This treatment should be followed by a half hour of reclining, during which light exercise of the toes and ankles is recommended in order to maintain the circulatory stimulation. Contrast plunges should be taken once a day and preferably as soon after working hours as possible. In more acute cases, they may be taken twice a day and followed with a local analgesic rub.

Special exercises are useful after subjective symptoms have subsided, before then exercises in which body weight is borne on the feet may do more harm than good. In the present studies not weak muscles but

strained and exhausted muscles are being considered. Therefore rest is more strongly indicated than extra work. Routine exercises may be used advantageously later, especially for their general tonic effect.

The clinical importance of the second phase of treatment cannot be overemphasized. Restricted activity, rest with the feet elevated, and stimulated circulation are essential measures toward overcoming painful symptoms. Naturally they are to be used coincidentally with the third phase of treatment, but with the clear understanding that mechanical devices are primarily protective and aimed at preventing a continuation or recurrence of faulty strains and stresses.

3 Disordered Mechanics—Various types of arch supports, pads, anterior bars, wedges and adhesive strappings have been employed with success for many years. Their use has been described so fully in the literature that present consideration may justifiably be given to two methods of treatment that have resulted from the present investigations. One method is adapted especially for the treatment of foot disorders in adults, while the other is suited more specifically to the "weak foot" condition in children. Both are easy in their application, and their effectiveness has been well demonstrated by several years of experimental use.

It has been shown that disorder in the longitudinal arch and also in the metatarsal portion of the foot originates as a functional deficiency of the first metatarsal, through either laxity of ligaments or shortness, this member lacks the necessary supporting contact with the ground. However, while that contact cannot be gained by the bone, it can be accomplished by raising the supporting surface beneath its head. Thus a proper degree of elevation will take up the slack in lax ligaments and cause the first metatarsal bone to assume its share of function and relieve correspondingly the overload on the second metatarsal (fig 5B), also such effective contact will reestablish the medial margin of structural stability and safeguard the muscles from abnormal strain. When the first metatarsal bone is short, the elevation has the effect of supplementing its length and thereby compensates for this type of fault.

An insole has proved to be the most practical medium for applying this principle. It includes the compensating feature in the form of a small platform, which is located under the head of the first metatarsal. Since the proper height of the platform can be determined only by trial, an insole permits easy removal for any necessary adjustments, while it maintains the platform securely in position when in use. This method makes no attempt to supply an artificial support which acts by assuming the weight stress that should normally be borne by the structure of the foot. It operates by creating a more natural distribution of the stresses to every segment of the foot, just as properly fitted glasses, by compensating for defects in the lens, restore normal vision through corrected distribution of light rays on the retina.

The second method, which is especially useful in children, employs a light piece of flexible metal covered with leather, whose base is located under the heel, and having an extension carried upward on the inner side of the foot to the region of the navicular bone. Body weight imposed on the heel is thus utilized through the extended portion to offer resistance to any tendency of the foot to roll into a pronated posture. As a result, stresses that would otherwise become concentrated on the second metatarsal are distributed on all four of the lateral metatarsals. This device, which may be called an

"arch control," does not establish function in the first metatarsal but protects this medial segment of the foot from the strains and progressive deformity of an unbalanced posture. When used in children, prevention of such strains affords the most favorable chance of a shortening adjustment of the plantar ligaments of this segment during the process of growth, so that effectual ground contact may subsequently develop. Here again there is no element of artificial support, the effort being to minimize abnormal function and to create conditions that are most likely to promote development along normal lines.

Mechanical devices should not be an added cause of pain. Any change in the distribution of weight will be accompanied with a sensation of strangeness, but proper adjustment should eliminate any feeling of actual discomfort from that source. When symptoms persist, it is well to check on the second phase of treatment as carried out by the patient. Too frequently the patient fails to realize its importance and with the first signs of relief subjects his feet to functional tests that interfere with steady improvement.

A snugly fitting, elastic-web band is a helpful accessory in cases in which effusion of the midtarsal joints is present and causes sharp pain along branches of the medial plantar nerve.

CONCLUSION

Instead of presuming all feet to be 100 per cent proficient, various degrees of limited capabilities must be recognized. Such feet are the ones that are predisposed to disorders, they become overstrained and develop subjective symptoms when exposed to the functional stresses that the more perfectly constructed foot can easily withstand.

The identification of primary causes as defects within the foot is most clearly revealed by an analysis of normal function of the foot and its earliest phases of disturbance. They comprise some form of deficiency in the first metatarsal segment, their presence and effects are demonstrable by x-ray examination and by physiologic tests.

Curative treatment as well as preventive care is more effectively based on correcting the original phases of functional disturbance than on the end results, as represented in a broken down mechanism.

Physicians have no reason to doubt their ability to treat the great majority of feet successfully, certainly they are far better qualified to do so than the agencies to which the public now flees. Every urban practitioner can find among his patients many individuals who would be benefited greatly by his help. The mechanics of foot trouble are not difficult to understand, and a few x-ray pictures will go far toward demonstrating that he can analyze these disorders and symptoms with confidence. Treatment then becomes almost an automatic procedure, but it must include systematic attention to each of the three sources of symptoms.

Responsibility for the more difficult and exaggerated cases may well be shared with, or referred to, the orthopedic surgeon. But as in other physical ailments these advanced cases will probably comprise less than 10 per cent of the number that the physician will be able to take care of without aid.

Mothers in particular will be grateful for any help and advice given to them regarding the feet of their children. In the latter, patience is far more necessary than the prescribing of special exercises. This is said advisedly because, in relying on the growth process,

permanent improvement is naturally slow, after suitable means of establishing improved function have been supplied, the general activities of children are usually sufficient for corrective development. On the other hand, disorders in adults may be more stimulating to one's interest because through the alleviation of subjective symptoms the results of treatment are more quickly apparent.

The foot is not an uninteresting organ. It possesses a record of man's prehistory which in completeness and in legibility surpasses that of any other structure in the body. Its modern weaknesses are no less interesting, they are widespread and justly entitled to qualified professional help.

Clinical Notes, Suggestions and New Instruments

INTERRUPTION OF INSULIN SHOCK THERAPY

ROBERT C. HUNT, M.D., AND HAROLD FELDMAN, M.D.
ROCHESTER, N. Y.

One of us recently had the opportunity of studying the technic of the insulin shock treatment of schizophrenia under the guidance of Dr. Manfred Sakel of Vienna. During this teaching demonstration it was observed that there were some patients who frequently failed to arouse from coma after the feeding of sucrose solution by stomach tube. We often waited well over an hour after tube feeding before resorting to intravenous injection of dextrose, which promptly and invariably restored the patients to consciousness. Since starting this form of therapy at the Rochester State Hospital, March 1, 1937, we have had the same difficulty. Four of the first nine patients treated frequently required intravenous injection of dextrose because of failure to arouse after stomach feedings of sucrose solution.

For convenience we have had our feeding solution prepared in 8 ounce (240 cc.) bottles, with concentrations varying according to the size of the dosage of insulin. The general rule has been 1 Gm. of sugar per unit of insulin. Since some of our patients required doses of from 150 to 200 units to produce satisfactory shock, it was necessary to make up sugar solutions of concentrations up to 80 per cent if the feeding was to be restricted to 8 ounces. After the repeated failure of some patients to arouse after these feedings, it occurred to us that this unphysiologic concentration of the solution might be responsible for its lack of absorption. Therefore, April 17 we began supplementing the feeding of sugar solution with about 10 ounces (300 cc.) of warm water. There was an immediate and striking acceleration of reaction from shock in every patient.

Data were analyzed on only the five patients who were fairly well stabilized on a shock dose for several days both before and after the change in technic. Three of these patients were good reactors who usually came out of coma after tube feeding without intravenous injection of dextrose. These three became fully awake from thirty-nine of the forty-one shocks preceding April 17 in an average of thirty-three minutes following tube feeding. Two of them required intravenous injection of dextrose once each, in an average of seventy-five minutes after tube feeding. When the feeding was diluted these three patients aroused from their next nineteen shocks in an average of eighteen minutes after feeding, and no intravenous injections were required.

The other two patients were poor reactors who usually required intravenous injections of dextrose to arouse them. In seventeen shocks preceding the change these two aroused without intravenous injections of dextrose only twice each, in an average of fifty-nine minutes after tube feeding. The other thirteen shocks, 76 per cent of the total, had to be terminated by means of intravenous injection of dextrose, in an average of fifty-three minutes after tube feeding. After the dilution technic was instituted these two aroused from eleven shocks

without intravenous injection of dextrose, in an average of forty-three minutes. They required intravenous injection of dextrose in only three instances, or 21 per cent of the total, and two of these injections were given within half an hour after tube feeding because of alarming physical conditions rather than because of delay in reaction.

We have not as yet used dextrose for the stomach feedings, although it is possible that it might be absorbed more rapidly than sucrose.

CONCLUSION

When one terminates therapeutic insulin shock with tube feedings of sucrose solution, more rapid absorption appears to take place if the solution is well diluted and warmed.

1600 South Avenue

MOLDED PLASTER SHELLS FOR THE REST AND PROTECTION TREATMENT OF INFANTILE PARALYSIS

GEORGE E BENNETT M.D. MILTON C COBEY M.D.
AND HENRY O KENDALL BALTIMORE

During the exhibition of the rest and protection treatment of infantile paralysis at the last session of the American Medical Association, many physicians requested that we report in detail the method of making molded plaster shells and covering them with a water-proof material which increases the life of a cast threefold.

Fig 1—Molded spica cast for the hip with adjustable foot plate

The principle employed by us in the treatment of anterior poliomyelitis is chiefly that of constantly maintaining the physiologic rest position for paralyzed muscles by means of protective supports. As muscle power returns, the weaker of two opposing groups is favored by the protection position, that is, the origin and insertion of the weaker muscles are brought as close as possible without injuring the opposing muscles or producing a permanent deformity by permitting bony or ligamentous changes. At the same time it is desirable that the protected parts may be bathed and given heat and light massage twice or three times a week. The combination of protection and treatment is possible only in a cast which has been bivalved, hence the use of bivalved casts.

The following is a brief description of the technic of applying the molded casts.

The skin is protected from the wet plaster by the use of either thin stockinet or talcum powder. The desired number of splints are held firmly together and thoroughly moistened by drawing them over the surface of the water in a pan. They should not be dropped into the water. A half cast is then made by molding the "specialist plaster splints" (Johnson & Johnson) to the part and holding it in position until it sets. This obviates the necessity of plaster-of-paris bandages. Then, with the plaster still moist, this half cast is removed without the mold being destroyed in any way. The shell is allowed to dry thoroughly with or without the aid of artificial heat. With the use of strips of specialist plaster, the rough edges are then covered and the cast reinforced at the points of greatest strain. To add greater strength to the casts, narrow strips of sheet metal may be molded to the contour of the outer surfaces of the cast and held firmly in place by strips of specialist plaster. When this fresh coat of plaster has been allowed to dry, there may be many rough areas inside and out. The entire cast may be rubbed smooth with a fine grade of sandpaper, obtaining thereby a fairly high polish of the plaster. The cast is now ready to be covered with the highly protective and strengthening coats of cellulose acetate.

The materials¹ used in the cellulose acetate mixture are cellulose acetate (lacquer viscosity 5), dimethyl phthalate A (or "sizing"), and acetone U S P (dimethyl ketone). In preparing the mixture, a 2 quart jar is two-thirds filled with the cellulose acetate flakes. To this is added 3 ounces of the sizing and the jar is then filled with the acetone. The jar is sealed and set aside for three or four hours, and the contents are stirred occasionally. The consistency will be slightly thicker than ordinary paint when it is first made, however, it will be necessary to add more acetone as the mixture is used because the acetone tends to evaporate from the jar as it is opened for use.

With an ordinary paint brush, the cast (which must be thoroughly dry) is painted with the cellulose acetate mixture. Three coats are usually applied, ample time being given—from five to ten minutes—for each coat to dry. Any rough places that appear after drying may be removed with fine sandpaper. It is not advisable to apply the cellulose acetate mixture on days of high atmospheric humidity, as the material will absorb moisture. With the absorption of moisture, the covering turns white and peels off because it does not adhere to the plaster.

The cast is fitted on the patient. It should fit snugly, giving equal pressure over the entire surface of the skin to avoid the occurrence of pressure ulcers. Straps of webbing and buckles are riveted on to the shell in the desired places and the rivet heads are touched with cellulose acetate to smooth the surface. The cast is now water proof, its strength is doubled and its life is trebled.

For adequate protection of muscles in patients convalescing from poliomyelitis, changes in protective supports are frequently needed to meet changes in muscle balance. Ordinary casts are not adjustable to meet these changes without application of entirely new molds. We have therefore incorporated metal with the plaster to make parts of the casts adjustable and eliminate the necessity of constantly changing the molds. Two of these will be described briefly.

Figure 1 shows a molded spica cast for the hip with an adjustable foot plate. In the preparation of the cast, the plaster mold for the foot is made separately and then connected by a metal strip to the cast for the leg. The metal strip is attached to the plaster molds with rivets before the cellulose acetate is applied. The malleable iron bar allows for adjusting the foot in plantar flexion, dorsiflexion, eversion, inversion or combinations of these positions. Adjusting the foot and ankle positions by bending the metal bar eliminates the possibility of distorting the position of the foot.

With close observation and careful checking of the muscle power, contractures are prevented and the equal return of power

Fig 2—Adjustable molded cast for the thigh

in opposing muscle groups can be brought about at approximately the same time by constantly adjusting the protective support to favor the weaker group.

Figure 2 shows an adjustable molded cast for the thigh, used to protect weak hip abductors or adductors. The sliding metal bars between the leg molds are held in any desired position by

¹ Cellulose acetate (lacquer viscosity 5) Celanese Corporation of America 180 Madison Avenue New York Dimethyl phthalate A Kay Fries 180 Madison Avenue New York Acetone U S P Any large pharmaceutical firm in Baltimore conveniently obtained from Muth Bros & Co 25 South Charles Street

a set screw. This cast may be used advantageously to maintain the frog leg position following reduction of congenitally dislocated hips, facilitating the gradual change from the position of marked abduction to the neutral position.

Protection is important in relation to the small muscles of the hand. To avoid the use of heavy casts, small cuffs have been devised to give maximum protection to isolated muscles with a minimum amount of weight and restriction of motion.

Figure 3 shows a cuff combining the protection for the opponens pollicis and lumbricales. When only the opponens muscles need protection, the lower plaster strip is omitted.

In making the opponens cuff, two strips of 3 or 4 inch special-1st plaster are folded lengthwise to a width of about 1 inch or less. The plaster is always folded before it is wet. Pieces of a tongue depressor split lengthwise are held laterally at the index and little fingers, and the strip of plaster is then wrapped around the hand above the metacarpophalangeal joints. The tongue depressor (or similar object) allows enough width so that the finished cuff will slide easily over the knuckles when the cuff is removed. The plaster band around the hand may be allowed to set before the thumb piece is added. For the thumb two strips of the 3 or 4 inch plaster are folded crosswise and then folded diagonally. This triangular piece is then molded

Fig. 3—Opponens lumbricales cuff

as a U under the thumb and held in the desired protection position. The plaster extends only to the distal phalanx (unless the extensor longus pollicis is weak), thus permitting use of the end joint in functional activity. When the lumbricales support is added, the lower band is placed below the metacarpophalangeal joints to prevent any pressure over the knuckles and permit freedom of motion in flexion.

Many other modifications are easily and simply developed. The cuffs are light, thin, water proof and very durable and facilitate the rest and protection treatment of paralyzed muscles.

Greenspring Avenue and Forty-First Street

A SUGGESTED TEST FOR CORTICAL ADRENAL CARCINOMA

ROBERT T. FRANK, M.D., NEW YORK

In the last few years the attention of the profession has been increasingly directed toward the group of patients classified under the terms of "adrenal cortical syndrome," "pituitary basophilic syndrome," and hirsutism complicated by symptoms resembling these groups. The most characteristic symptoms are general hirsutism, plethora, high blood pressure, abdominal obesity, pink or bluish abdominal striae, amenorrhea and enlargement of the clitoris, and osteoporosis.

In 1934 I¹ reported the presence in high concentration of estrogenic substance in the urine of two patients with advanced and disseminated adrenal cortical carcinoma. Both of these cases came to autopsy.² Since then the urines of patients with

various diseases showing some of the symptoms just mentioned have been similarly tested. Fifteen gave a negative reaction. A summary of the conditions is given in table 1. Only two further positive reactions were obtained. These occurred in patients who were found to have adrenal cortical carcinoma. In table 2 are shown the positive reactions so far obtained (in four patients), which include both the previous and the present report. The intensity of the reaction is likewise indicated.

TABLE 1—Negative Reactions

Hirsutes obesity increased blood pressure amenorrhea	♀	6
Hirsutes obesity, increased blood pressure amenorrhea, striae negative intravenous pyelogram osteoporosis	♀	1
Obesity hypertension striae operation and autopsy (normal adrenals)		1
Essential hypertension		2
Child aged 5½ years obesity hypertension 150 mm		1
Hypernephroma (with operation)		1
Adrenal medullary paraganglioma (with operation)		1
Adrenal cortical adenoma (with operation)		1
Adrenal hyperplasia (with operation)	♀	1

As further controls the urines of more than 500 other patients in which the bio assay for estrogenic substance was performed showed no such high concentration. The maximum even in the cases of menorrhagia and metrorrhagia in which our studies³ have shown an excessive ovarian function have not shown a concentration of 1 mouse unit of estrogenic substance in less than 3 cc of urine. Moreover, among the number of adrenal tumors such as adrenal cortical adenoma, adrenal medullary paraganglioma and adrenal hyperplasia, the elevation of estrogenic substance never reached this level.

From these observations it seems likely that adrenal cortical carcinoma alone of adrenal tumors increases the amount of estrogenic substance in the urine to as high as from 1,000 to 10,000 mouse units per liter, with a negative pregnancy test. These observations are therefore again presented as a possible help in diagnosis. The rarity of the condition makes it impossible for any one investigator to obtain a large number of observations.

The performance of the test is extremely simple. A fresh specimen of urine is obtained. Of this a total of 1 and 2 cc is injected subcutaneously in five divided doses spread over forty-eight hours into adult castrated mice (0.2 cc × 5, 0.4 cc × 5). After completion of the injections, the vaginal spreads are examined three times daily for three succeeding

TABLE 2—Positive Reactions

	No. of Cases	Cc of Urine Giving Positive Test
*Adrenal cortical carcinoma (previous report) (autopsies)	2	0.075
†Adrenal cortical carcinoma without symptoms (operation)	1	0.2
‡Adrenal cortical carcinoma (adrenal syndrome) (operation and autopsy)	1	0.1

* Reference 2

† Patient operated on by Dr. Richard Lewisohn; no endocrine symptoms well two years.

‡ Patient operated on by Dr. Edwin Beer; typical adrenal cortical syndrome; early cortical carcinoma breaking through capsule. Died two months after operation. Autopsy.

days. A positive estrogenic reaction manifests itself by the change of the vaginal spreads from leukocytes to cornified epithelial cells. In every case the urine must likewise be tested either by the Friedman or by the Aschheim-Zondek technic. The pregnancy test must be negative if any conclusions are to be drawn.

A positive mouse reaction in quantities of 1 and 2 cc of urine which corresponds to at least 500 to 1,000 mouse units of estrogenic substance per liter, should be considered strong evidence in favor of adrenal carcinoma. If the test is positive in these quantities, it should be performed with smaller quantities until the lowest positive level has been reached.

SUIPESTIFER SEPTICEMIA AND MENINGITIS COMPLI CATING MENINGOCOCCIC SEPTICEMIA AND MENINGOCOCCIC MENINGITIS

M M RAVITCH M D, AND J A WASHINGTON M D, BALTIMORE

Since 1931 there have been at the Harriet Lane Home twenty-eight cases of infection with the suipestifer bacillus. Almost all the patients were Negro children. Only three deaths occurred. The source of the infection is yet unknown, and it is interesting that several of the patients were nursing infants. Most of the cases (more than three fourths) were instances of primary infection with this organism, while in a few a suipestifer septicemia followed some other infection, most often pneumonia. The commonest picture was that of a paratyphoid-like fever. Complications most commonly seen were pyarthroses and suppurative and nonsuppurative osteomyelitis. Thrombocytopenia and purpura occurred twice. Specific symptoms were absent. Diagnosis was made usually by blood culture. Specific agglutinins for the organism are developed by most patients. The case herewith reported is of particular interest in that it presents a rare manifestation of the suipestifer infection.

REPORT OF CASE

C H, a Negro girl, aged 4 years, was admitted to the Harriet Lane Home Jan 29, 1936, with a meningococcic infection seven hours after the appearance of the first symptom. The previous evening the mother had entered a hospital with proved meningococcic meningitis.

On admission the sensorium was clear, the neck was supple, the Kernig sign was questionable, the reflexes were hyperactive,

Temperature and treatment chart in case reported

and typical fresh petechiae were seen on the arms, trunk and palpebral conjunctivae. The temperature was 105.0 F. Lumbar puncture yielded a clear, Pandy-negative fluid containing only one cell per cubic millimeter. No organisms were seen in the smear. Antimeningococcus serum was given intrathecally. To this can be attributed the subsequent appearance, within a few hours, of cervical rigidity, retraction of the head and a positive Kernig sign. Culture of the cerebrospinal fluid grew meningococci by the succeeding day. The initial blood culture also grew meningococci. Though no history of diarrhea was obtained, the child had two diarrheal stools the first afternoon. The next morning the spinal fluid was cloudy, and although it contained 1,600 cells per cubic millimeter, 97 per cent of which were polymorphonuclears, it proved sterile on culture. A second blood culture, taken that evening, twenty-four hours after admission, instead of the meningococcus, yielded *Salmonella* suipestifer in pure culture. The admission cultures were still on hand and still showed undoubted meningococci. Furthermore, transplants of these original cultures, sent according to the regular practice at the Harriet Lane Home to the National Institute of Health in Washington, D C, were identified as cultures of meningococcus group I. In the following sixteen days, ten of eleven blood cultures taken were positive for suipestifer, one taken in the middle of this period being reported sterile.

On the third day lumbar puncture was attempted on two occasions, each time resulting in the withdrawal of bloody fluid.

From the Harriet Lane Home of the Johns Hopkins Hospital and the Department of Pediatrics, Johns Hopkins University School of Medicine.

Cultures of the fluid were sterile. On the fourth day lumbar puncture again yielded a bloody fluid, which this time contained the suipestifer organism in pure culture. In the next eleven days on each of the nine occasions when culture of the cerebrospinal fluid was made, the suipestifer organism was obtained.

It is interesting that the white blood cell count, 30,500 on admission, had fallen to 4,500 on the sixth day, and the granulocytes had fallen from 93 to 74 per cent. This is in accordance with the observation of mild granulocytopenia as a common event in suipestifer infection.

Antimeningococcus serum was given intrathecally and intramuscularly the first four days. The patient was profoundly prostrated, had a high irregular fever, and was constantly in a most desperate condition. She was given large blood transfusions, repeated lumbar punctures, and finally forced spinal drainage. In brief, she overcame violent serum sickness, thrombophlebitis, pneumonia and myocardial failure with gallop rhythm and recovered. A temporary lumbar subarachnoid block also occurred. The child was discharged, entirely well, forty-eight days after admission to the hospital.

The agglutinations of the blood against *Salmonella* suipestifer group II were as follows: twenty-first day 1:80, thirty-third day 1:320, forty-second day 1:2,560, seventy-fifth day 1:1,280, one hundred and sixty-fifth day 1:1,280. Cultures of stool and urine were negative, as has been the usual experience in the suipestifer infections in the Harriet Lane Home.

COMMENT

In an attempt to probe the literature for other certain cases of suipestifer meningitis we found only three. Kuttner¹ reported fatal meningitis in a white man, uncomplicated so far as was known by other disease. From the spinal fluid *Bacillus* suipestifer was cultured in the Biological Laboratory of the Medical Division of this hospital. Similarly, Materna and Januschke² identified as B suipestifer an organism obtained from blood, organs and cerebrospinal fluid of a man who died of purulent meningitis. Further details are not given by them. Recently Boycott and McNee³ have reported a fatal case of suipestifer infection in an English woman in whom the meningitis was discovered at postmortem examination. Death occurred after a two months illness, marked by chills and fever, bone and joint pains, abdominal rigidity and mental confusion. B suipestifer was cultured from the blood in life, and after death from the blood, spleen and gallbladder as well as from the meninges, which showed a purulent exudate over the vertex.

Although more than eighteen other cases of meningitis due to a gram-negative, motile, bipolar staining rod were found, the reports date from the postwar years and all depend on the identification of Neukirch's⁴ bacillus *Erzindjan* with the Glaser-Voldagsen organism and the acceptance of that organism in turn as a suipestifer strain.⁵

SUMMARY

A 4 year old Negro girl with meningococcic septicemia and meningococcic meningitis had only meningococci in the blood on the first day of disease and *Salmonella* suipestifer alone in the blood on the second day. The latter infection of the blood stream persisted at least fifteen days. Possibly dependent on

gross contamination of the cerebrospinal fluid with blood in the course of lumbar puncture, suppurative meningitis developed and lasted for twelve days. The uniquely benign outcome of the suppurative meningitis can perhaps be attributed to the strong antibacterial meningeal reaction set up by the meningococcal meningitis and intrathecal serum treatment. The low spinal fluid cell count with mononuclear predominance is noteworthy.

Special Clinical Article

CARDIOVASCULAR SYPHILIS

CLINICAL LECTURE AT ATLANTIC CITY SESSION

JAMES E. PAULLIN, MD

Professor of Clinical Medicine, Emory University School of Medicine
ATLANTA, GA

Involvement of the cardiovascular system accounts for a large group of persons who suffer the most disabling effects of latent syphilis. Is it any wonder then that particular attention should be directed not only to the control of syphilis but equally to prevention of the devastating effects of cardiovascular disease in persons who have acquired the infection?

Essentially, a consideration of cardiovascular syphilis means a discussion of syphilitic aortitis and its complications, such as aortic insufficiency, aneurysm, narrowing of the ostia of the coronary arteries and, rarely, involvement of the heart muscle. Since all these conditions are latent manifestations of an infection acquired many years previously, naturally they are most frequently unsuspected and are unrecognized before it is too late for treatment to be of curative value.

Spirochaeta pallida, the causative organism, is distributed from the primary lesion through the blood stream to all parts of the body. Infection undoubtedly takes place in the aorta, as well as in other organs of the body, rather early in the disease. When the aorta is so invaded there may develop, rather rarely, an acute inflammatory reaction in the aorta with marked degenerative changes causing death within six or eight months after the primary lesion. One case was observed in our clinic in which a gummatous lesion developed in the cusp of an aortic valve, producing rupture and death within eight months after the initial infection. However, such cases are exceptional, and as a general rule there is a latent period of from ten to twenty years before the infected person manifests any symptoms or signs referable to his cardiovascular system.

FREQUENCY

Syphilitic aortitis, from the standpoint of the pathologist, is a disease recognized far more frequently at autopsy than in the clinic. Its incidence in different parts of the country varies with the character of the population. Since syphilitic infection is far more prevalent in Negroes than in other races and since it occurs more frequently among the ignorant and the indigent, it naturally follows that aortitis is most commonly found in these groups, although the fact that syphilis is no respecter of persons must not be forgotten. From statistical data collected by Turner¹ it would seem that approximately 10 per cent of all

patients with latent syphilis will have demonstrable clinical evidence of cardiovascular involvement. In a series of 6,253 cases of syphilis in a late stage collected by the Cooperative Clinical Group,² approximately 619, or 10 per cent, of the patients had cardiovascular syphilis on admission or acquired it later. The wonder is that a far greater number did not give clinical manifestations. Warthin³ and his associates have observed at autopsy that the aorta is involved, either macroscopically or microscopically, in approximately 90 per cent of persons with latent syphilis. The age group most frequently affected is that between the ages of 30 and 55 years, although cases may occur earlier and some even later. However, it should constantly be remembered that every person who has syphilis is an excellent candidate for cardiovascular involvement.

PATHOLOGY

Pathologically, aortitis is recognized as the late lesion which produces disability. The aorta is invaded by means of the lymphatics accompanying the vasa vasorum, the process begins in the adventitia and is followed later by degenerative changes occurring in the media. Since the ascending aorta and the aortic arch are most bountifully supplied with lymphatics, it is natural that these areas should be the ones most frequently involved. The degenerative process usually begins just above the aortic valves and extends either upward or downward. As the infection progresses, there is marked destruction of the elastic and connective tissues composing the media, resulting in focal degenerative areas which may remain small or may be fairly extensive. Along with this change there is reparative fibrosis, resulting in marked scarring and producing considerable deformity of the aorta. As the lesion progresses the intima becomes thickened by a proliferation of connective tissue, so that the inner surface of the aorta is thrown into ridges, which extend up and down its long axis, and resembles very much the bark of a tree. With long standing infection marked scarring occurs, together with a weakening of the aortic wall. Occasionally one sees atheromatous changes associated with it. As a result of the progression of this pathologic process, several complications may develop which add to its seriousness.

Syphilitic aortic insufficiency results when there is a downward extension of the aortitis involving the commissures of the semilunar valves. The commissures are widened, causing a separation of the valves and resulting in insufficiency. Sometimes this lesion is the only visible one of syphilitic involvement. Occasionally a small gumma involving the leaflet of the valve will occur. Frequently the syphilitic process may extend into the valve itself, producing insufficiency.

Syphilitic aortitis may cause extensive narrowing of the orifices of the coronary arteries, at times almost obliterating them. I have frequently observed both coronary ostia to be so small that they would admit only a bristle, sometimes one orifice is involved without the other. As a result of the partial or complete occlusion of the coronary ostia, patients frequently have attacks of angina pectoris, suffer paroxysmal dyspnea or even die suddenly.

Aneurysm results when the medial coat of the aorta becomes so completely destroyed as to withstand no longer the intra-aortic pressure. The involved aortic

wall begins to give or stretch. If the syphilitic process is diffuse, general aortic dilatation results and a fusiform aneurysm is formed, but if the medial degeneration is localized over a smaller area, a saccular aneurysm results. Saccular aneurysms vary in size from those of only a few centimeters in diameter to those that almost completely fill the upper part of the chest. The coronary arteries may be involved after leaving the aorta, although such involvement is rare according to my experience.

Involvement of the myocardium does not appear with anything like the frequency of aortic involvement. Three types of lesions in the myocardium are distinguished. First, a localized gumma may occur in any part of the heart. It is seldom recognized and rarely gives any symptoms of its presence unless it occurs in an area involving the conducting system. In such a location it will cause varying degrees of heart block. Second, a diffuse generalized acute inflammatory condition may be observed. It was described first by Warthin⁴ and later by me.⁵ It is characterized by numerous well defined translucent areas scattered throughout the myocardium, chiefly in the ventricles. The heart muscle in the involved areas is completely destroyed, and patients with this type of syphilitic infection usually die suddenly. Third, the type of lesion which occurs most frequently in younger persons is the fibrotic type, in which the heart muscle, in the absence of gross coronary obstruction, is replaced in part by an overgrowth of connective tissue, evidently an attempt at healing. The integrity of the heart muscle is so completely destroyed that it is no longer able to act efficiently. The ventricles dilate slowly but gradually, compensation is lost, the heart is never able to become again a perfectly functioning organ and the patient dies of progressive cardiac insufficiency.

RECOGNITION OF CARDIOVASCULAR SYPHILIS

Every person who has had syphilis, whether treated adequately, indifferently or not at all, should be suspected of having involvement of the cardiovascular system. Of those who have had no treatment or of those who have had inadequate treatment, approximately 25 per cent will show a variable degree of aortitis. In those who were seen early and who have been treated adequately, the aortic involvement occurs very, very rarely.

In the detection of syphilitic aortitis, too much reliance must not be placed on the presence of a positive Wassermann reaction or on any other serologic test for syphilis. It is well known that from 10 to 20 per cent of persons with latent cardiovascular syphilis will give a negative serologic reaction. It is of the utmost importance to be able to recognize aortitis before the development of its complications. Admittedly this is extremely difficult to do, yet it can be done with a fair degree of accuracy provided the physician will first suspect the existence of the disease and then take a sufficient amount of time to investigate each patient thoroughly. A good general rule to follow is first to suspect its presence and then to prove that it does not exist before dismissing the diagnosis. Of great help in making the diagnosis is the history given by the patient. In the early stage of the disease there is usually no complaint, although, when the patient is closely questioned, mention is made of oppression in the chest, usually referred

beneath the upper part of the sternum, noticed most frequently after exercise or any excitement and lasting only a short time. This type of pain does not radiate and frequently is accompanied by a slight hacking cough or a desire to take a deep breath. When there is marked thickening about the ostia of the coronary arteries, more severe and radiating pain occurs, that typical of angina pectoris. In the absence of pain, a history may be obtained of decreasing ability to take exercise without becoming short winded or of attacks of paroxysmal dyspnea, coming mostly at night during sleep.

Physical examination may reveal surprisingly little but one may find a slight increase in the retromammary area of dullness and occasionally a loud metallic tambour-like aortic closure. Fluoroscopic examination of the chest may show nothing, or it may show slight dilatation of either the ascending aorta or the aortic arch. A patient who has not had rheumatic heart disease and does not have hypertension, but who does give a history of syphilitic infection and presents any three of the aforementioned symptoms or signs, even in the absence of a positive Wassermann reaction, should receive the benefits of antisyphilitic treatment.

TREATMENT

If every person who acquires syphilis could receive the benefits of adequate treatment, such as has been outlined by the Cooperative Clinical Group,⁶ there would be few patients with cardiovascular manifestations of latent syphilis. Moore⁷ said "In a large series of patients admitted with primary and secondary syphilis and followed for a considerable number of years thereafter, none who have received as much as three courses of arsphenamine plus interim heavy metals subsequently developed clinically recognizable cardiovascular syphilis." The best treatment then is to prevent the development. Until such prevention, which I hope is not far distant, is accomplished, it is necessary to consider what line of procedure will be most beneficial for the patient with this type of latent syphilis.

Until a few years ago it was a controversial question whether patients with aortitis, aortic insufficiency or aneurysm should receive antisyphilitic treatment at all. Such a point of view arose in the minds of practitioners when they observed that this type of patient frequently became progressively worse when treated vigorously with arsenicals. Many physicians can remember distressing results that followed the administration of arsenicals to patients with aortic insufficiency or with aneurysm. Sudden death was not unusual, rapid progress of the disabling condition was frequently observed and a good many patients without treatment lived longer than those with specific treatment. Since then better methods have been outlined which promise more to the patient in the relief of symptoms, the prolongation of life and the prevention of complications, than was possible ten years ago.

A patient with cardiovascular syphilis should be subjected to the usual forms of treatment that are prescribed for any patient with heart disease, that is, his habits and mode of living should receive attention, the amount and character of exercise should be discussed and other general hygienic measures should be taken for his comfort. As to specific treatment, patients may be divided into two groups, those who have a normally

⁷ Moore J. E. The Modern Treatment of Syphilis. Springfield Ill., Charles C. Thomas, 1933.

functioning myocardium and those who have congestive heart failure. In the latter group the congestive failure must receive immediate attention, and the remedies employed in treating patients who have this condition as the result of any other cause are freely utilized. When the pathologic process has advanced so far as to cause congestive failure, the patient will profit less from anti-syphilitic treatment.

In planning any form of treatment for the patient with cardiovascular syphilis, it is of the utmost importance to be sure that the measures employed will do no harm. In the wards of the Emory University Division of Grady Hospital and in the outpatient department under the supervision of Dr. L. M. Blackford, one sees many patients with aortic insufficiency and aneurysm who have never had any antisyphilitic treatment, a few who have had indifferent treatment and none who have had adequate treatment. Many of these patients are critically ill when first seen. As a result of this experience over a number of years, these patients are treated from four to six months with potassium iodide by mouth and intramuscular injections, at weekly intervals, of either a mercury or a bismuth compound. Arsphenamine is not given in any form whatsoever until the patient has had the preliminary treatment. At the end of this period, according to the nature of the lesion and the condition of the patient, one may begin the administration of small doses of neoarsphenamine, starting with 0.1 Gm and never exceeding 0.3 Gm. In cases of uncomplicated aortitis, larger doses of neoarsphenamine may be given during the second period of intravenous medication, provided there is no evidence of involvement of the coronary ostia. To obtain the most satisfactory results, every patient with cardiovascular syphilis should receive continuous weekly treatments for at least eighteen months.

If the patient when first seen has cardiovascular syphilis and congestive heart failure, antisyphilitic treatment must be undertaken with the greatest care. Potassium iodide is given by mouth as soon as possible, and smaller doses of the heavy metals at weekly intervals. In the Grady Hospital clinic, because of the type of patients who have the disease and their general inherent characteristics, it is impossible to give accurate statistical data on the end results of this type of therapy. However, statistical data collected by the Cooperative Clinical Group^a in a large series of cases of uncomplicated syphilitic aortitis show that the average duration of life for untreated patients was thirty-four months, for those adequately treated eighty-five months and for those inadequately treated fifty-six months. Of those adequately treated, 63 per cent were living and symptom free. The life of patients with aortic insufficiency who received adequate treatment was prolonged from forty to fifty-five months, for patients with aneurysm who received adequate treatment, the average duration of life was increased from thirty-seven to seventy-five months.

My experience leads me to believe that as a result of treatment many patients are made symptom free and live longer than they otherwise would.

SUMMARY

1 Involvement of the cardiovascular system occurs in approximately 10 per cent of patients with latent syphilis.

2 Beginning as aortitis, it may lead to aortic insufficiency, aneurysm, narrowing or occlusion of the coronary ostia or myocarditis.

3 Adequate treatment of early syphilis will prevent cardiovascular involvement in practically all patients.

4 The early recognition of aortitis before complications occur and the institution of adequate treatment prolong life and relieve symptoms.

5 Patients with cardiovascular syphilis should receive for the first four to six months potassium iodide by mouth and intramuscular injections of either a mercury or a bismuth compound, at the end of this period small doses of neoarsphenamine may be given.

6 Treatment should be continued at weekly intervals for at least eighteen months to accomplish the best results.

1010 Medical Arts Building

Council on Pharmacy and Chemistry

PRELIMINARY REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING
PRELIMINARY REPORT
PAUL NICHOLAS LEECH, Secretary

TRISODARSEN (FORMERLY TRIARSEN)

Under the name "Triarsen," the Abbott Laboratories presented for the Council's consideration a brand of Trisodium Arsphenamine Sulfonate, with the following probable formula:

The firm stated that the product was not being marketed but was being supplied to investigators as "Preparation #1529." Subsequently, at the suggestion of the Council, the firm adopted the name "Trisodarsen" for the product, which is not being actively marketed but is supplied to investigators.

Trisodarsen is proposed for use in the treatment of syphilis in the same manner as neoarsphenamine. It is stated to be considerably more stable in air than neoarsphenamine and sulfarsphenamine. The maximum tolerated dose, administered intravenously, for rats is reported to be between 500 and 600 mg per kilogram of body weight. The maximum tolerated dose for neoarsphenamine is between 240 and 400 mg per kilogram.

TABLE 1—Average Time and Treatment Necessary
for Reversal of Blood Wassermann
Reaction to Negative

	Cases	Average Total Dosage Grams	Average No of Injections	Average No of Days
Arsphenamine	103	3.9	9.7	75
Neoarsphenamine	110	7.1	13.4	99
#1529	40	4.18	8.0	58.7

It appears that single doses of 25 mg of Trisodarsen per kilogram cure experimental rabbit syphilis. The firm states that the average dose for man is from 0.45 to 0.6 Gm, for women, from 0.3 to 0.5 and 0.6 Gm is recommended, administered intravenously.

The firm informed the Council that Dr. John H. Stokes and Herman Beerman had been working on the product about three and three-fourths years. The total number of cases treated was 165 and the number of injections given 2,675, the total number of injections per patient was from one to fifty-five. Eighty-two per cent of forty cases with blood serologic reversal to negative were reported to be reversed by the tenth injection of the drug.

With seropositive primaries, the time in days for reversal to negative was reported as somewhat longer than with arsphenamine and shorter than with neoarsphenamine. With cases of secondary syphilis the time for reversal to negative was shorter

than with arsphenamine and much shorter than with neoarsphenamine. In both groups the number of cases studied was comparatively small.

The firm presented Moore's condensation of the figures of Cannon and Karelitz as in table 1, adding data on preparation #1529.

For healing of lesions of early syphilis, the firm presented Moore's condensation of the earlier data of Cannon and to it added for comparison preparation #1529 (table 2).

TABLE 2—Average Time and Treatment Necessary for Disappearance of Visible Lesions

Cases	Average Total Dosage Grams	Average No of Injections	Average No of Days
Arsphenamine (32)	1.3	2.7	14
Neoarsphenamine (61)	3.8	5.8	23
#1529 alone (53)	1.35	2.7	14.6
#1529 and bismuth (62)	1.05	2.66	15.0

Disappearance of Spirochetes—According to data presented by the firm the organisms in primary lesions with 0.3 Gm of Trisodarsen disappear in from twenty-four to ninety-six hours and with 0.6 Gm in from twenty-four to thirty-six hours. With secondary syphilis, using 0.3 Gm, in more than forty-eight to seventy-two hours, and using 0.6 Gm, more than forty-eight hours and less than ninety hours.

Reactions—A drug may be able to satisfy all the requirements of potency and yet not be free from reactions. According to information supplied by the firm there seemed to be no particular effect from Trisodarsen on the kidneys or blood in the patients studied. However, seventy-five of the 165 patients treated had one or more reactions. Nausea and vomiting was seen in thirty-three cases and was so severe that it was necessary to stop the drug in twelve cases, 8 per cent of the whole. Moreover, nitritoid reactions were observed in thirteen cases, 8 per cent of the whole. There was also one mild case of dermatitis, one moderate case and two severe cases of dermatitis were observed. Various other reactions in smaller numbers were observed. Cole and his workers in 1931 found that, in 1,212 cases with 78,350 injections, reactions were observed with 15 per cent of patients treated with arsphenamine and 16.7 per cent treated with neoarsphenamine. With #1529 this rose to 45.5 per cent. Cutaneous reactions with #1529 were one in 1,338 injections, as against Moore's finding of dermatitis—one in 1,857 with arsphenamine and one in 5,367 with neoarsphenamine. The firm states that recent lots of the drug show lessened incidence of reactions.

Chemotherapeutic Consideration—In rabbit syphilis Trisodarsen in a dosage of 0.025 Gm per kilogram gave 100 per cent cures. The firm stated that the maximum tolerated dose for rats lies between 500 and 600 mg. Trisodium arsphenamine sulfonate is less toxic than neoarsphenamine. This is referred to later.

The Abbott Laboratories apparently present sufficient experimental evidence on arsenicals to give an idea of the value of Trisodarsen for syphilis in rabbits. The firm states that it is apparently less toxic than neoarsphenamine. Unfortunately, animal experiments cannot always be transferred to man and this seems to be particularly true with preparation #1529. Probably the prime requisite of any antisyphilitic agent is first its freedom from reactions. With #1529 the investigators themselves state that they are three times as frequent as those observed after arsphenamine and neoarsphenamine. Moreover, while the drug has been studied by two expert syphilologists, Stokes and Beerman, the material thus far (at the date of the referee's first report to the Council) comprises but 165 cases and 2,675 injections.

There is no question that the development of more antisyphilitic agents is desirable. They must be, however, both potent and safe. If they are no more potent than agents now available, certainly much will depend on their relative safety.

As a result of its first consideration, the Council felt that by all of these criteria Trisodarsen, though promising, is not yet ready for general use. The Abbott Laboratories was informed of the Council's belief that a preliminary report dealing with such an apparently toxic product would be unwise. The firm was further informed that, as long as marketing of the product

was held in abeyance, any report by the Council would also be held in abeyance, pending further investigation specially along the lines of the toxicity of the product.

Subsequently the firm submitted a later paper by Drs Stokes and Beerman, reviewing a total of 189 cases treated with 3,009 injections. This was transmitted to the Council for its consideration only in part, the report in its entirety having been submitted to the *Archives of Dermatology and Syphilology* for publication. The firm submitted this material in the hope that the additional data would justify a preliminary report by the Council.

The Council's referee examined this portion of the report by Drs Stokes and Beerman on the drug Trisodarsen, which has been investigated by a single observer on a fellowship grant for four years. He found that the drug apparently has an animal chemotherapeutic index of 18 and, as used on 189 patients with 3,009 injections, seemed to give as satisfactory results from the standpoint of its spirillicide effect as other arsenicals.

The reaction incidence of the drug, as shown by these further clinical investigations in comparison with other arsenicals, indicates that it produces as little reaction of the immediate or mild type as arsphenamine, neoarsphenamine and mapharsen. It is perhaps somewhat more reaction producing than neoarsphenamine when the latter is used under the best technical administration. It is suggested that, like sulfarsphenamine, Trisodarsen may produce more dermatitis than neoarsphenamine. This requires suspended judgment.

Herxheimer effects are apparently rare. No injuries to special sense organs have been noted. In rate of healing of primary and secondary lesions, Trisodarsen compares favorably with other arsenical preparations and seems to have a favorable effect on the blood serologic tests in early syphilis. Moreover, the incidence of relapse of a clinical and serologic type is low and would compare well with figures for continuous treatment with other preparations.

Investigators admit that clinical examination of Trisodarsen is incomplete, as its use has been confined for the present to early syphilis, and no report has been attempted on latent cardiovascular, prenatal and neurosyphilis.

In view of the further clinical studies, the Council voted to postpone further consideration of Trisodarsen to await the availability of more corroborative evidence and authorized publication of the foregoing preliminary report.

REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH Secretary

VIOSTEROL (A R P I PROCESS) IN OIL

Under the name Viosterol (A R P I Process) in Oil, American Research Products, Inc., a branch of General Mills, Inc., markets a solution in oil of ergosterol activated by the action of low speed electrons produced by suitable controlled electrical means. The finished product is adjusted to contain not less than 10,000 U S P units of vitamin D per gram. The firm presented satisfactory evidence of the clinical efficacy of the product. In addition the firm presented reports of comparative animal feeding tests of massive doses of vitamin D which show no differences in toxicity between preparations containing crystalline vitamin D, Viosterol (A R P I Process) and Viosterol produced by the Steenbock process. While these results do not prove that vitamin D is the same chemical substance in the three products, taken together with the clinical evidence already presented the results indicate that the antirachitic effect of Viosterol (A R P I Process) in Oil in therapeutic doses is the same as that of ergosterol otherwise activated in oil. The firm has signified its intention of carrying out further chemical investigations of the product, which will be considered by the Council.

The Council has recently revised its definition of viosterol to include products activated by other than ultraviolet irradiation. This therefore makes Viosterol (A R P I Process) in Oil eligible for acceptance. The firm, however, does not market the product as such to physicians but sells the prepara-

tion to concerns for incorporation in other products. Other firms have now submitted products containing Viosterol (A R P I Process) in Oil for the Council's consideration.

The Council recognizes Viosterol (A R P I Process) in Oil acceptable as an ingredient of otherwise acceptable marketed products in which it is incorporated for its antirachitic effect.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED

FRANKLIN C BING Secretary

SQUIBB YEAST TABLETS

(DRIED BREWERS' YEAST AND MALTED WHEAT GERM EXTRACT)

Manufacturer—E R Squibb & Sons, New Brunswick, N J

Description—Dried brewers' yeast and malted wheat germ extract (essentially maltose, dextrines and "starch intermediate products") in tablet form

Manufacture—A strain of brewers' yeast high in vitamins B and G is grown on specially prepared hop free wort containing sugars, grain extractives and nutrient salts, centrifuged, washed several times and spray dried. The resulting powder is mixed with malted wheat germ extract (Squibb Vitavose, THE JOURNAL, Aug 6, 1932, p 477) and compressed into tablets.

Analysis (submitted by manufacturer)—Moisture 4.0%, ash 6.5%, protein ($N \times 6.25$) 42.0%, fat (ether extract) 1.4%, crude fiber 0.0%, carbohydrates (by difference) 46.1%

Calories—37 per gram, 105 per ounce

Vitamins—Biologic assay shows a potency of 50 International units of vitamin B₁ and 20 Sherman units of vitamin G per gram

CHALLENGER BRAND EVAPORATED MILK

Distributor—Sewell's United Stores, Salt Lake City

Packer—Page Milk Company, Merrill, Wis

Description—Unsweetened, sterilized evaporated milk, the same as Page Evaporated Milk (THE JOURNAL, May 30, 1931, p 1872)

BLAIR'S BEST FLOUR PHOSPHATE ADDED

Manufacturer—Blair Milling Company, Atchison, Kan

Description—Bleached red winter wheat containing 0.5 per cent monocalcium phosphate

Manufacture—Selected red winter wheat is cleaned, scoured, tempered and milled by essentially the same procedure as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with nitrogen trichloride (one ninth ounce per 196 pounds) and with a mixture of benzoyl peroxide and calcium phosphate (1 pound to 50 barrels of flour)

Analysis (submitted by manufacturer)—Moisture 13.0%, total solids 87.0%, total ash 0.9%, fat (ether extract) 1.0%, protein ($N \times 5.7$) 9.3%, monocalcium phosphate 0.5%, crude fiber 0.2%, carbohydrates other than crude fiber (by difference) 76.1%

Calories—35 per gram, 99 per ounce

OLAC

Manufacturer—Mead Johnson and Company, Evansville, Ind

Description—A spray-dried, pasteurized, homogenized mixture of skim milk, Dextrin-Maltose, olive oil, calcium caseinate, and halibut liver oil

Manufacture—Skim milk from tuberculin tested cows is mixed in formula proportions with Dextrin-Maltose and calcium caseinate. The mixture is pasteurized, cooled, mixed with formula proportions of olive and halibut liver oils, homogenized

under 2,500 pounds pressure, spray dried, and packed in sterilized cans hermetically sealed under nitrogen

Analysis (submitted by manufacturer)—Moisture 1.0%, total solids 99.0%, ash 3.5%, fat (ether extract) 18.6%, protein ($N \times 6.38$) 23.5%, crude fiber 0.0%, carbohydrates other than crude fiber (by difference) 53.4%

Calories—48 per gram, 136 per ounce

Vitamins—The vitamin A content of Olac (furnished by halibut liver oil) is approximately 1,400 U S P units per ounce powder. Other vitamins are present as they occur in skim milk powder

Claims of Manufacturer—A proprietary food designed for the feeding of premature and new-born infants, particularly those deprived of breast milk, under the direction of a physician

(1) ANN PAGE SPARKLE VANILLA ICE CREAM DESSERT POWDER

(2) ANN PAGE SPARKLE CHOCOLATE FLAVORED ICE CREAM DESSERT POWDER

(3) ANN PAGE SPARKLE CHOCOLATE FLAVORED PUDDING

(4) ANN PAGE SPARKLE VANILLA PUDDING

Packer—Quaker Maid Company, Inc, New York

Distributor—The Great Atlantic and Pacific Tea Company, New York

Description—(1) A powdered mixture containing sugar, skimmed milk powder, vanilla extract, Karaya gum, certified color and salt

(2) A powdered mixture containing sugar, cocoa, Karaya gum and salt

(3) A powdered mixture containing sugar, corn starch, cocoa, powdered skim milk, salt and vanilla

(4) A powdered mixture containing cane and corn sugars, corn and arrowroot starches, vanilla extract, salt and certified color

Manufacture—The dried or granulated ingredients are mixed and mechanically filled into moisture-proof parchment paper bags, which, in turn, are inserted into tightly sealed cartons wrapped in cellophane

Analyses (submitted by manufacturer) —

	(1) per cent	(2) per cent	(3) per cent	(4) per cent
Moisture	0.4	1.1	3.1	3.1

(4) 3.83 per gram, 109 per ounce

1 BOSWELL'S BEST BRAND HAWAIIAN PINEAPPLE SLICED

2 BOSWELL'S BEST BRAND PINEAPPLE JUICE

Distributor—Boswell Grocery Company, Kilgore, Texas

Packer—Hawanan Pineapple Company, Ltd, San Francisco

Description—1 Canned pineapple packed in concentrated pineapple juice with added sucrose. The same as Dole Hawaiian canned pineapple products (THE JOURNAL, April 8, 1933, p 1106)

2 Canned Hawaiian pineapple juice retaining in high degree the vitamin content, the same as Dole Hawaiian Finest Quality Pineapple Juice (Unsweetened) (THE JOURNAL, June 3, 1933, p 1769)

SATURDAY, OCTOBER 2, 1937

SULFANILAMIDE—A WARNING

Seldom has any new drug introduced in medical practice aroused the enthusiasm that has developed for sulfanilamide. Much of this enthusiasm is warranted. The drug is truly remarkable, as indicated by startling results reported in the treatment of various infections. Indeed, its coming has stimulated research in pharmacology and biochemistry to a remarkable degree. Moreover, as is customary, departments of research associated with the manufacture of pharmaceutical products have already taken to the long trail of studying similar and associated preparations and derivatives to find something better or just as good which they can call all their own. When these derivatives appear for sale, the optimistic advertising departments will extol them as far superior to sulfanilamide itself. The therapeutic or toxic properties of new drugs cannot be predicted from their chemical formulas. Experience indicates that many of the new drugs will be without therapeutic advantage over the nonproprietary sulfanilamide, some may enhance such undesirable side reactions as granulocytopenia or severe damage to the erythrocytes. In Europe, similar research is being done on nitroso compounds and various derivatives. Out of the mass of developed preparations may come some drugs of merit. Until plenty of evidence is available, however, as to the virtues and dangers of such products, the medical profession may well be skeptical. Many months of investigations of the pharmacology, toxicology, and clinical application of new preparations under carefully controlled conditions are needed to provide evidence of therapeutic value. Some of these new compounds may have a higher chemotherapeutic index than does sulfanilamide as far as mice, for instance, are concerned. Care must be taken, nevertheless, in applying to man toxicity figures based wholly on animal experiments.

THE JOURNAL, the Council on Pharmacy and Chemistry and various individual practitioners have warned against indiscriminate use of sulfanilamide. Apparently these warnings have been insufficient. In THE JOURNAL, September 25, eleven contributions on

sulfanilamide were published. Nine of these reported the occurrence of toxic manifestations, including dermatitis and photosensitization of the skin. Particularly serious are the possible dangers of granulocytopenia and sulfhemoglobinemia. The latter may sometimes go unrecognized without adequate methods of diagnosis. The complication originally called enterogenous cyanosis, thought to be due to "intestinal toxemia," has been shown to be due to the presence of sulfhemoglobin or methemoglobin in the blood.

Sulfanilamide should not be administered in association with other drugs until definite information is available as to toxic effects. Thus far only the harmlessness of sodium bicarbonate in such association seems to have been established. Magnesium sulfate and some of the coal tar derivatives are conspicuously drugs which should not be administered concurrently.

Premature publicity for this drug has, as usual, been unfortunate. The startling news reports that the administration of sulfanilamide will "cure" gonorrhea in forty-eight hours has led to some unpleasant results. Responsibility lies considerably with pharmacists who are willing to sell dangerous drugs to anybody over the counter.¹ In one large city, hospitals have admitted young men with severe sulfhemoglobinemia resulting from self medication with sulfanilamide. The physician must bear in mind the potential hazards of this drug.

SPIROCHETAL JAUNDICE

The probability that spirochetal jaundice, or Weil's disease, will become a disease of importance in this country has already been pointed out.¹ Ample evidence of the widespread geographic distribution and actual hazard from the disease has appeared in many different journals. Three cases of Weil's disease were reported in 1937 for the first time in Canton, China. Zuelzer² reviewed fourteen cases of the disease occurring in 1934 in Denmark. In thirteen of these there was definite icterus but, as she pointed out, only about 40 to 60 per cent of all patients with Weil's disease have recognizable icterus. From Japan, Germany, Austria, South America, France and Soviet Russia⁴ cases of the disease have also been reported. Davidson and his colleagues⁵ reported nineteen cases

¹ Sulfanilamide has been sold under a number of brand names. The physician realizes that products marketed under brand names are exactly as dangerous as those sold as sulfanilamide. Occasionally Prontosil is mentioned as a proprietary brand of sulfanilamide. Prontosil is not sulfanilamide but is a derivative of sulfanilamide which apparently breaks down in the body to sulfanilamide.

of spirochetal jaundice in fish workers in Aberdeen. Thirteen of these patients were employed definitely in the handling and cleaning of fish. These observations show that workers among fish must be included among the occupational groups especially liable to Weil's disease. Wolstencroft⁶ reported a case in a canal worker in England, so that this work also must be considered hazardous in this respect. Another unsuspected source of leptospiral infection was reported in the Northumberland and Durham coal mines by Swan and McKeon.⁷ In that report, twelve cases of the disease were found among miners, with a mortality of 33 per cent. There was a history of working in damp, rat-infested seams in all except one case. According to Alston and Brown,⁸ in a paper read February 26, 1937, 142 authenticated instances of the disease in an obvious clinical form were reported in the British Isles during the preceding three and a half years. Twenty-one occupations or circumstances were involved and the case fatality rate was 15 per cent.

In Australia also the disease has made its appearance. In October 1933, according to Cotter,⁹ at Ingham, North Queensland, appeared the first of a series of outbreaks of a disease that was regarded as entirely new to that district and which was diagnosed clinically as Weil's disease. This was the first known occurrence of the disease in Australia. This area of North Queensland is the sugar cane area. The favorable climatic conditions and the presence of infected rodents will almost certainly cause this disease to become endemic, Cotter believes, and constitute a constant danger to the health of the workers in the fields. More recently Clayton and Derrick¹⁰ reported a case of "seven day fever" in a patient living near Pomona, South Queensland. The diagnosis was based clinically on the similarity of the patient's symptoms with those of "seven day fever" patients of the East and pathologically on the isolation of a leptospira from the patient's blood. This leptospira, however, proved to be different from a strain isolated in North Queensland and was distinguished by its lower virulence and the absence of cross agglutination. There exist in Queensland, therefore, at least two distinct kinds of leptospiral disease.

Distance in wars and epidemics frequently lends a false sense of security, as has been repeatedly illustrated for both phenomena. In the case of leptospiral jaundice, however, there is sufficient indication that the incidence of the disease in the United States is increasing and even now its incidence is such as to constitute a problem for preventive as well as curative

medicine. Thus Jeghers and his associates¹¹ reported a case with postmortem observations and also reviewed the American cases up to 1935. From this compilation of the reported American cases it can readily be seen, they state, that each case represents a clinical picture which, in spite of minor variations, resembles the classic European and Japanese types of the disease. Occupations of the twelve patients reported up to that time were of interest in that the group included a sewer worker, a member of a swimming team, a cook, a laborer and a fish cutter. Contact with rat-infested buildings was mentioned several times. In one instance the disease developed after the patient had been soaked in rain water. Failure to recognize the disease probably accounts for the report of so few cases in the United States. As they pointed out, the true incidence and future course of spirochetal jaundice in this country will be better determined if the following conditions are fulfilled. The disease must be suspected more often and the variation in symptomatology appreciated, all suspected cases should have laboratory confirmation, laboratories (both public health and hospital) should be prepared to make the necessary diagnostic tests, and serum and prophylactic measures should be utilized when indicated.

In October 1934, according to a report in *THE JOURNAL*, May 9, 1936, an outbreak of jaundice occurred among the students attending a religious novitiate in St. Louis County, Mo.¹² This outbreak involved thirty-two students out of a total of 132. *Leptospira* morphologically identical with *Leptospira icterohaemorrhagiae* was readily demonstrated in samples of water obtained from holy water fonts. While the causal relationship between the leptospira and the outbreak of jaundice could not be proved, it was in some respects of suspicious nature and might in fact be similar to the milder of the two diseases reported from Australia.

In San Francisco¹³ late in 1935, two men working as cribbers in the city sewers became ill and were subsequently diagnosed as having spirochetal jaundice. In March 1937 four more cases of the disease were reported in rapid succession in that city. These cases were entirely unrelated and in different localities. The clinical diagnoses were confirmed by laboratory examination. The examination of rats, by the George William Hooper Foundation for Medical Research, in the vicinity of one case indicated approximately 33 per cent infected by the spirochetes. It seems likely that, if equal care is taken to make a correct diagnosis in cases of obscure jaundice, other cities will find similar cases. Furthermore, if public health authorities carry out investigations on rodent infestation elsewhere, the reservoir in animals may be found high in many parts

13 Personal communication from Dr. J. C. Geiger, director of public health.

of the country. It seems certain, from the facts of the last three years, that spirochetal jaundice is at least as great a hazard as potentially adjudged three years ago. Individual cases of this disease, while probably more frequent than is generally supposed, are still of sufficient rarity to warrant their careful study and reporting. Any general outbreaks of jaundice are at least partially the responsibility of public health agencies and demand thorough bacteriologic, serologic and rodent examinations.

Current Comment

END RESULTS OF RESPIRATOR TREATMENT

The immediate dramatic results of the use of respirators in failing pulmonary function has received too much attention to necessitate reemphasis. The eventual issue in patients who have received this form of treatment, especially over prolonged periods, is not so well understood. Thus Wilson¹ reported that, in six children who had paralysis of the intercostal muscles and the diaphragm from poliomyelitis without complications, the Drinker respirator was efficient in maintaining pulmonary ventilation for long periods. The use of the machine, however, for nine children with bulbar paralysis without intercostal involvement, although it seemed helpful, was often ineffective. Only two of these nine children survived. In such cases, therefore, he recommends that the machine be employed only as an emergency measure and after every attempt has been made to free the pharynx from secretions. Except for moderate emphysema found at necropsy in three patients with bulbar paralysis, there was no evidence discovered of harm due to its use. Legg² was impressed with the life saving character of the machine in respiratory involvement due to infantile paralysis but noted that a considerable number of patients who survived developed deformities of the chest and many failed to recover the power of voluntary expansion of the chest. Smith,³ in a paper published in 1933, noted that data received from various orthopedic hospitals and convalescent homes revealed that about one third of the respirator patients died and that the cause of death on the hospital records was given as bronchopneumonia. All of twelve patients with bulbar lesions reported by Brahdy and Lenarsky⁴ died. Among thirty-four patients with spinal lesions only, twelve died in the respirator and four within six weeks after treatment. Equally discouraging is the report by Crone⁵ on twenty-four patients with acute poliomyelitis treated in the Drinker respirator. Of the nine having involvement of respiratory muscles only, five died and four survived. Of the ten patients with bulbar involve-

ment all died, and, of the five with both mechanisms affected, three died and two survived. Landon⁶ has reported eighty-eight cases of poliomyelitis treated in the respirator, death occurring in fifty-three in the hospital, a mortality rate of 60.2 per cent. Of the thirty-five patients treated in the respirator able to breathe without difficulty and without artificial aid, sixteen, or 45.7 per cent, had died at the end of eighteen months, practically all of them from respiratory infections. According to another study by Brahdy and Lenarsky,⁷ twenty-seven of sixty-three patients treated in respirators were discharged from the hospital. Twelve of these twenty-seven patients who survived the hospital treatment died at intervals of from two weeks to two and a half years afterward. All of them had residual paralysis of some of the respiratory muscles. Seven of the surviving patients were either bedridden or greatly limited in their physical activities. Seven others alive at the time of reporting were well enough to attend school and two had no residual paralysis whatever.

ORAL VACCINES IN THE "COLD" SEASON

The pharmaceutical business has never been accused of lacking in perspicacity. If one firm seems to be putting over a product, creditable or not, other firms take to the trail. Every seasonable ailment is greeted with preparations, old, new or merely revived. Summer is officially over, and the "season of colds" is already being exploited. During the winter of 1936-1937 Eli Lilly & Co. strenuously advocated the treatment of colds with an oral vaccine, Entoral. Since colds are generally self limiting, scientific evidence on the value of any preparation is hard to obtain. The Council on Pharmacy and Chemistry considered Entoral¹ and pointed out

After a consideration of the available evidence it would seem that the hypothesis on which "Entoral" is based is inadequately supported by experimental evidence and that the reports of its use contained in the literature are insufficiently documented. For these reasons the Council declared "Entoral" unacceptable for inclusion in New and Nonofficial Remedies.

Now the William S. Merrell Company has been circularizing the profession with claims broader and more bombastic than those made for Entoral. Its product is Catarrhal Orava-Merrell described as catarrhal vaccine in enteric coated tablet form. The firm claims that "by the use of Catarrhal Orava it is now possible to immunize large industrial groups against Common Cold at extremely low cost." Where is the evidence? Has any competent industrial surgeon actually established the usefulness of this preparation? Recent advertising mentions only experiments on Merrell's own employees.¹ Is it not likely that the firms hope to have the doctors introduce their oral vaccine preparations to the public as so many other nostrums or preparations of unestablished value have been introduced in the past?

WISCONSIN'S HALL OF HEALTH

The State Medical Society of Wisconsin, in connection with its annual meeting at Milwaukee during the week of September 14, held an exhibit on health for the public. The "Hall of Health" occupied the main arena of the Milwaukee Auditorium, opening Friday evening September 10 and closing Friday evening September 17. Eighty exhibits were shown, including those of the State Medical Society of Wisconsin, the Medical Society of Milwaukee County, the Woman's Auxiliary, state and local health departments, educational institutions including Marquette University, the University of Wisconsin and national organizations including the American Medical Association, the American Society for the Control of Cancer, the American College of Surgeons and the National Board of Medical Examiners. Special exhibits on roentgenology, sight conservation (Hall of Sight), dentistry, nursing and pharmacy were shown by the several societies of specialists and professional workers. The Camp transparent woman was shown and demonstrated. Motion pictures were running in several of the exhibits, as were special demonstrations of the subjects exhibited. The Wisconsin Anti-Tuberculosis Association displayed its traveling educational exhibit built in a trailer coach. The exhibit was opened with a radio broadcast by an announcer from station WTMJ, who took a portable transmitter into the hall and interviewed the exhibitors as he passed from booth to booth. Newspaper publicity was liberal, intelligent and prominently featured. The public reaction, awaited with interest because of the pioneer nature of this venture under state medical society auspices, was gratifying. The total attendance, estimated from entrance checks and a photoelectric cell counter at the door of the Hall of Sight, exceeded 101,000. Long lines of waiting people formed before the exhibits on cancer, syphilis, embryology, dentistry, nostrums and quackery, health and hygiene, and before the Hall of Sight. Crowds gathered about the transparent woman at every demonstration. The seats in the several motion picture rooms were well filled at most times. Through this venture the State Medical Society of Wisconsin sets a high standard. All important mediums of health education were used and coordinated effectively—the exhibit, the pamphlet, the motion picture, the personal demonstration, the healthmobile, the newspaper and the radio. With a strictly educational and noncommercial policy, it was found possible to get liberal cooperation both in personal service and in financial assistance from the professional groups alone, without contributions from outside sources except the loan of a few exhibits of definitely educational character from commercial sources—lent without advertising or other consideration. In view of the strictly educational nature of the project, the city of Milwaukee donated the use of the auditorium. In some communities health shows are being planned under the sponsorship of local medical societies and in association with health supplements to be issued by leading newspapers. Here the newspaper supports the show, the medical profession determining ethical problems and scientific exactitude. Health education is a major function of the medical profes-

sion. With this venture, the State Medical Society of Wisconsin has demonstrated not only that the profession is able and willing to discharge that function but that the public is eager to accept leadership from responsible sources.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH)

ARKANSAS

Pellagra Survey—Four northern counties of Arkansas have been selected as the area for a survey of pellagra now being conducted by the U. S. Public Health Service in cooperation with the American Red Cross.

Personal—Dr. John J. Andujar, Harrisburg, Pa., has been appointed assistant professor of pathology at the University of Arkansas School of Medicine, Little Rock.—Dr. William B. Grayson, Little Rock, has been reappointed state health officer for a second term of four years.

Society News—A round table discussion on infantile paralysis and syphilis was conducted before the Arkansas County Medical Society in Stuttgart, August 10, by Drs. William B. Grayson, state health officer, Thomas T. Ross, assistant state health officer, Arthur M. Washburn, director, division of communicable diseases, and Walter Myers Smith, director, division of maternal and child health, all of Little Rock.—The Southeast Arkansas Medical Society was addressed at McGehee, July 22, by Dr. Irving J. Spitzberg, Little Rock, on childhood tuberculosis.—The Seventh Councilor District Medical Society was addressed at a meeting in Malvern, August 10, by Drs. George B. Fletcher, Hot Springs National Park, infantile paralysis, and Shelby B. Hinkle, Little Rock, recent advances in obstetrics.

CALIFORNIA

Personal—Karl F. Meyer, Ph.D., chairman of the department of bacteriology and director of the Hooper Foundation for Medical Research, University of California, San Francisco, has been awarded the honorary degree of doctor of medicine at the University of Zurich, Switzerland, his alma mater.

Insects Retain Plague Infection at Least Ten Months—Dr. Walter M. Dickie, director of public health of California, Sacramento, reported to the U. S. Public Health Service, August 9, that specimens of fleas, ticks and lice, taken from ground squirrels (beecheyi) in San Mateo County during September 1936 and stored in the icebox until July of this year, produced typical plague infection when inoculated into guinea-pigs.

DELAWARE

State Medical Meeting at Wilmington, October 11-12—The Medical Society of Delaware will meet at the Academy of Medicine, Wilmington, October 11-13. In addition to clinics at the Wilmington General and St. Francis hospitals, the following will present papers:

- Dr. Lang W. Anderson, Wilmington: Urology. Its Relation with General Medicine.
- Dr. Joseph M. Barsky, Wilmington: Simplified Diabetic Management—A New Regimen.
- Dr. William W. Babcock, Philadelphia: Practical Points in Relation to Clinical Surgery.
- Dr. John J. Cassidy, Wilmington: Pneumonia.
- Dr. Frederic H. Leavitt, Philadelphia: The Danger of Preoperative Delay in Suspected Brain Tumor Cases.
- Dr. George M. Piersol, Philadelphia: Some Aspects of Visceral Syphilis.
- Dr. Brooke M. Anspach, Philadelphia: The Causes and Treatment of Uterine Bleeding.
- Dr. Philip F. Williams, Philadelphia: Cardiac Diseases in Pregnancy with Special Reference to Maternal Deaths from Cardiac Diseases.
- Mr. J. B. McManus, Wilmington: Industrial Law.
- Dr. William Zentmayer, Philadelphia: The Importance of an Eye Examination in the Fourth Decade of Life.
- Dr. Robert H. Ivy, Philadelphia: Tumors of the Mouth and Jaw.

Dr. Charles P. White, Wilmington, will deliver his presidential address Tuesday evening. The New Castle County Medical Society will act as host to the state society during the meeting and Governor Richard C. McMullen will give the address of welcome.

DISTRICT OF COLUMBIA

Dr Overholser to Superintend St Elizabeth's Hospital—Dr Winfred Overholser, formerly commissioner of the Massachusetts State Department of Mental Diseases, Boston, has been appointed superintendent of St Elizabeth's Hospital, succeeding the late Dr William A White. Recently Dr Overholser has been director of the division of mental hospital research of the National Committee for Mental Hygiene. A native of Massachusetts, Dr Overholser graduated at the Boston University School of Medicine in 1916. Until 1924 he served at the Evans Memorial Hospital and the Westborough, Gardner and Medfield state hospitals. From 1925 to 1930 he was director of the division for the examination of prisoners and was assistant commissioner from 1930 until 1934, when he became commissioner. This position he held until late in 1936. He taught psychiatry at his alma mater for several years and has been lecturer at the Boston University of Law since 1929. He served as consultant to the National Crime Commission and as chairman of the committee on delinquents and prisons of the first International Congress of Mental Hygiene. He has been a member of the Committee on Psychiatric Jurisprudence of the American Medical Association since 1929. He is a past president of the Massachusetts Psychiatric Association and in 1936 was president of the New England Society of Psychiatry.

GEORGIA

District Meeting—The Fifth District Medical Society will meet at the Academy of Medicine, Atlanta, October 7, and hear the following speakers:

Dr George W Fuller Atlanta Surgery in Syphilis of the Stomach
Dr Alfred Blalock Nashville Tenn Surgical Treatment of Certain Types of Heart Disease
Dr William G Hamm Atlanta, Observations on Secondary Repair of Harelip
Dr Paul H Ringer Asheville N C Evolution of the Treatment of Tuberculosis

Dr Henry Clifford Sauls, Atlanta president of the Fulton County Medical Society and Dr George A Traylor, Augusta, president of the Medical Association of Georgia, will open the session.

ILLINOIS

Society News—At a meeting of the Kankakee County Medical Society in Kankakee, September 9, Dr Clark W Finnerud, Chicago, discussed "Diagnosis and Treatment of Common Skin Diseases"—Dr Philip F Schneider, Evanston, addressed the Bureau County Medical Society in Spring Valley, September 14, on "Progress in Obstetrics and Gynecology."

Chicago

Personal—Dr Rudolf Schindler, associate clinical professor of medicine, Division of Biological Sciences, University of Chicago, has been promoted to be associate professor of medicine, and Dr Louis Bothman clinical professor of ophthalmology.

Society News—Dr Charles C Dennie, Kansas City, Mo., will be the principal speaker at the first meeting of the season of the Chicago Medical Society, October 13, his subject will be "The Immunological Aspects of Syphilis"—At a meeting of the Chicago Laryngological and Otological Society, October 4, the speakers will include Drs Archibald L Hoyne on "Use of P-Aminophenylsulfanilamide in the Treatment of Scarlet Fever Carriers", John A Bigler, Highland Park, Ill., "Blood Cell Response to Sulfanilamide Therapy," and George S Livingston, "Sulfanilamide Therapy in Otolaryngology"—The Chicago Council of Medical Women was addressed October 1 by Drs Lucille H Snow, Evanston, Ill., on "Cancer in Women" and Bertha Van Hoosen, "Maternal Mortality"—Dr David A Horner was chosen president-elect of the Chicago Gynecological Society at its recent annual meeting and Dr George de Tarnowsky was installed as president. Dr Edward D Allen is secretary.

INDIANA

New Officers of State Medical Board—Dr Leslie C Sammons, Shelbyville, was elected president of the Indiana State Board of Medical Registration and Examination at a meeting September 15 in Indianapolis. Newspapers reported He succeeds Dr Jesse W Bowers, Fort Wayne, who was chosen secretary. E O Peterson, D O La Porte was elected vice president, and Dr William C Moore, Muncie, a new member of the board, treasurer. Other new members include Harry K McIlroy, D C, Indianapolis, and Dr Henry O Bruggeman, Fort Wayne.

New Division of Psychiatry—A division of child psychiatry has been created in the state board of health through the cooperation of the state welfare department, the Indiana State Medical Association, the state department of public instruction and the Indiana University School of Medicine, Indianapolis. Dr Elsie Elizabeth Welsch, who has been associated for the past two years with the Philadelphia Child Guidance Clinic and has completed an internship at the Institute of the University of Pennsylvania, has been appointed director of the new division. A program will be established to deal chiefly with the preventive aspects of child psychiatry and to include consultation services to rural schools wherever special problems arise and where special schools or training are not available. In addition, a psychiatric clinic will be held regularly in connection with the outpatient department of the Riley Hospital for Children, Indianapolis, and arrangements have been made to teach the subject to the students at the school of medicine. Dr Welsch graduated from Indiana University School of Medicine in 1932.

KENTUCKY

Changes in Hospital Superintendents—Dr Elbridge L Busby, superintendent of the Western State Hospital, Hopkinsville, has been transferred to the Central State Hospital, Lakeland. Dr James B Markey, now acting superintendent at Lakeland, has been appointed to succeed Dr Busby at Hopkinsville.

State Medical Election—Dr William E Gardner, Louisville, was chosen president-elect of the Kentucky State Medical Association at its annual meeting in Richmond September 13-16, and Dr Henry G Reynolds, Paducah, was installed as president. Vice presidents were elected as follows: Drs Robert Sory, Richmond, Elbert W Jackson, Paducah, and Frank M Stites Jr, Louisville. The 1938 meeting will be held in Louisville.

MICHIGAN

Society News—Dr William T King, Ahmeek, was elected president of the Upper Peninsula Medical Society at its annual meeting in Houghton, August 19-20. Sault Ste Marie was chosen as the place for the 1938 meeting.—Dr Wendell G Scott, St Louis, discussed "The Kymograph" before the Muskegon County Medical Society, September 17, in Muskegon.

Graduate Short Course in Obstetrics—A refresher course in obstetrics will be conducted in five areas of the Upper Peninsula, beginning October 4, under the auspices of the Michigan Department of Health, the department of postgraduate medicine of the University of Michigan, Ann Arbor, and the county and district medical societies. The five centers are Sault Ste Marie, Escanaba, Marquette, Houghton and Ironwood, where lectures in obstetrics will be given one evening each week for four weeks. The five lecturers are:

Dr Howard H Cummings assistant director of postgraduate medicine at the university. Care of the Pregnant Woman and Management of Toxemias and Other Complications of Pregnancy
Dr Norman R Kretschmar assistant professor of obstetrics and gynecology. The Conduct of Normal Labor
Dr Harold A Furlong Pontiac Hemorrhagic Complications of Pregnancy and Labor Including Placenta Praevia and Postpartum Hemorrhage
Dr Alexander M Campbell Grand Rapids Other Complications of Labor Including Prolonged Labor Difficult Labor Forceps Version and Operative Deliveries

Dr Furlong and Dr Campbell are members of the maternal health committee of the state medical society, the latter being chairman.

MISSOURI

Marriott Memorial Pediatric Fund—Plans are under way to create the Marriott Memorial Fund for Research in Pediatrics, in honor of the late Dr Williams McKim Marriott, formerly professor of pediatrics and dean of Washington University School of Medicine, St Louis. The following are members of a committee in charge of the project: Dr Malvern B Clopton, George R Throop, Ph D, Philip A Shaffer, Ph D, present dean of the medical school, Dr Alexis F Hartmann and Dr Park J White Jr. Persons wishing to contribute to the fund are asked to send their donations or pledges to any member of the committee or the dean's office of the university. Checks should be made payable to the university. In addition to the endowment to serve in his memory, a portrait of Dr Marriott has been procured to hang in the St Louis Children's Hospital. The cost of the portrait will be paid from the principal of the fund while the income from the remainder will be devoted to research in the field of pediatrics. Dr Marriott served as professor of pediatrics at Washington from 1917 to 1936 and as dean from 1923 to 1936.

Tuesday Is "Medical Day" in Kansas City—A series of graduate courses will be presented by the Jackson County Medical Society at the Kansas City Municipal Hospital number 1 over a period of forty weeks during 1937-1938. The first course opened September 14 with psychoanalysis as the subject. As Tuesday has been designated "Medical Day" in Kansas City, the courses will be held each Tuesday, a different number of weeks to be allotted to each subject. The one dealing with psychoanalysis will run for six weeks, with Dr. George Leonard Harrington as instructor. Other subjects to be considered in future programs will include diabetes endocrinology, immunology, electrocardiography, roentgenographic interpretation, physical diagnosis, bacteriology, clinical chemistry, postmortem examinations, hematology, interpretation of laboratory work, recent advances in laboratory diagnosis, tumors and urinalysis. A course on legal medicine will be conducted by members of the Kansas City Bar Association. From 5 to 6:30 each Tuesday for twenty consecutive weeks, a medical speakers' clinic will be conducted by the society to include practical instruction and practice in the essentials of speechmaking. Albert H. Johnstone, formerly director of the school of speech of the Horner Conservatory and College, is the instructor.

NEW YORK

Promotions in the Health Department—Dr. Vivian A. Van Volkenburgh, health officer in charge of the Ithaca district, has been promoted to be assistant commissioner of local health administration, and Dr. Ernest L. Stebbins, in charge of the Rochester district, to be director of communicable diseases in the New York State Health Department.

Three Cases of Psittacosis—Three cases of psittacosis in one family in upstate New York were reported in *Health News* September 13. The first case was in the father of the family, who raised birds as a hobby and had an aviary of more than 100 birds. He had not allowed any one else than himself to care for the birds until he became ill July 1 after which his wife and daughter took charge of them. Subsequently they also became infected with psittacosis. Investigation revealed that about two weeks before the man became ill several types of birds had died of unexplained illnesses. The source of the infection had not been determined at the time of the report.

New York City

Fifth Health Center Opened—The new Richmond Health Center at St. George, Staten Island, fifth of the city health department's district health centers, was dedicated September 14 with Mayor La Guardia and Dr. John L. Rice, city health commissioner, as the principal speakers. The building, financed with PWA funds of \$336,436, has four floors with space for maternity, child, dental, tuberculosis and social hygiene health services, as well as bureaus of general administration, records, preventable diseases and laboratories.

Lectures on Heart Disease—The New York Heart Association of the New York Tuberculosis and Health Association announces that its second series of lectures for practicing physicians on diseases of heart will be presented at biweekly intervals during the winter. The first lecture will be by Dr. Irving R. Roth, Tuesday afternoon, November 9, on "Management of Patients with Heart Disease" in the Blumenthal Auditorium at Mount Sinai Hospital. The course is open to all practicing physicians without registration or admission fee.

Hospital Bequest—Mount Sinai Hospital will receive \$916,579 as the residuary legatee under the will of the late Marco Fleishman, a tobacco merchant, according to an appraisal reported recently. The will provided that the bequest is to be known as the Rosetta and Marco Fleishman Fund and will be used for the construction and equipment of a new building or extension of the existing buildings to care for persons in the early stages of tuberculosis. In addition to this bequest, the hospital is to receive the principal of trust funds amounting to \$270,000 on the deaths of various persons for whom the trusts were created.

OHIO

State Association Organizes Speakers' Bureau—The Ohio State Medical Association has organized a speakers' bureau to assist county and district medical societies in obtaining outside talent for their programs. Later it is expected that the facilities of the bureau may be made available for meetings of allied and lay groups. The new bureau was organized as a part of the activities of a new committee on education, of which Dr. Clyde L. Cummer, Cleveland, is chairman. The subcommittee on the speakers' bureau is composed of Drs.

Russel G. Means, Columbus, chairman, Hubert C. King, Lakewood, Howard H. Minor, Steubenville, William M. Singleton, Portsmouth, and Karl D. Figley, Toledo.

Northwestern Ohio Annual Meeting—The ninety-third annual meeting of the Northwestern Ohio Medical Association will be held in Lima, October 5. A preliminary announcement lists the following speakers:

Dr. John S. Coulter, Chicago, Physical Therapy in Treatment of Arthritis
Dr. Raymond C. McKay, Cleveland, Treatment of Tuberculosis in the Sanatorium and in the Home
Dr. Sidney M. McCurdy, Columbus, The Relation of the Industrial Commission to the Physician
Dr. Walter H. Hartung, Columbus, Syphilis Control in Ohio
Dr. Carroll S. Wright, Philadelphia, Treatment of Syphilis
Dr. Dean D. Lewis, Baltimore, subject not announced
Dr. Frederick C. Irving, Boston, subject not announced

PENNSYLVANIA

District Meetings—The annual meeting of the Second Council District of the Medical Society of the State of Pennsylvania was held September 16 at the Plymouth Country Club near Norristown, with the following speakers: Drs. John O. Bower, Philadelphia, on "Radicalism versus Conservatism in the Management of the Acute Abdomen", Richard A. Kern, Philadelphia, "Clinical Allergy," and Chauncey L. Palmer, Pittsburgh, chairman of the state society committee on public health legislation, "Legislative Activities."—The west section of the Fifth Council District held its thirty-first annual meeting in Carlisle, September 16. Dr. Edward L. Bortz, Philadelphia, chairman of the state society committee on pneumonia control, gave an address on "Pneumonia Control—A Major Responsibility of the General Practitioner", Dr. Walter F. Donaldson, Pittsburgh, secretary of the state society, "The State Medical Society Reports to Its Components," and Dr. Harvey F. Smith, Harrisburg, "Acute and Chronic Appendicitis as Related to the General Practitioner."

Philadelphia

Four Solicitors for Fake Hospital Drive Sentenced—Four men were sentenced to jail terms September 22 following their conviction of carrying on a fake hospital charity drive for the "Naturopathic Hospital," in which they collected about \$30,000, newspapers reported. Fourteen men and a woman were arrested last April after an investigation by a Philadelphia newspaper and the Better Business Bureau. It was said that a group of promoters conducted the campaign from two hotels by telephone, selling tickets to a dance which was to have been held April 30. In their appeals the solicitors impersonated physicians and sold the tickets on the plea that the money was to be used for care of patients with infantile paralysis. During the trial it was pointed out in the newspapers that the "Naturopathic Hospital" had no beds for patients, but did have electrical and what "seemed to be surgical equipment." The state contended that the hospital was only a blind for the racket that paid its operators 97 per cent of the money contributed. Thomas J. Goldberg, superintendent of the "hospital," Harry S. Nurock, secretary of the Pennsylvania Society of Naturopaths, and Charles Reichner, a promoter, received sentences of two years each, and Robert Hoffman, the chief promoter, one year in the county jail. Charles L. Thomson, a solicitor, received a suspended sentence and George Brent, another solicitor, had his sentence deferred because he was reported to be ill in a hospital. These six men were convicted May 11. Of nine others on trial, the judge acquitted seven and the jury two. Those who were convicted have appealed to the supreme court.

Pittsburgh

Hospital News—The annual "Mercy Day" celebration at Mercy Hospital was held September 23 with Mayor Gen. Charles R. Reynolds, surgeon general, U. S. Army, Washington, as the speaker on "Medicine in the Military Service."

Society News—The first fall meeting of the Allegheny County Medical Society was held at the Mellon Institute Auditorium September 21 with Dr. Fred H. Albee, New York, as the guest speaker on "The Importance of the Lever at the Top of the Femur and Its Surgical Importance."

TENNESSEE

Society News—Dr. William F. Copeland, Cornersville, addressed the Giles County Medical Society, Pulaski, August 28, on enuresis.—Among speakers at a meeting of the Dyer, Lake and Crockett Counties Medical Society in Dyersburg, September 1, were Drs. Edward B. Smythe, Tiptonville, on

"Zinc Protamine Insulin in the Treatment of Diabetes Mellitus", John E. Frazier, Newbern, "Sulfanilamide and Allied Chemicals" and Bernard W. Patton, Dyersburg, "Syphilis"—Dr. James L. Heffernan, Jellico, addressed the Campbell County Medical Society, LaFollette, August 26, on sulfanilamide.

UTAH

State Medical Meeting and Election—The forty-third annual meeting of the Utah State Medical Association was held in Salt Lake City, September 24, with headquarters at the University of Utah. The guest speakers were:

- Dr. William B. Carrell, Dallas, Texas: Treatment of Knee Disability Resulting from Injury to Crucial or Collateral Ligaments and from Faulty Muscle Support; Treatment of Fractures of the Neck of the Femur.
- Dr. Henry Hunt Searls, San Francisco: Closure of Surgical and Traumatic Wounds; Modern Concept of the Pathologic Diagnosis and Treatment of Thyroid Diseases.
- Dr. Winchell McK. Craig, Rochester, Minn.: Importance of Adequate Treatment in Injuries of the Head; Influence of Early Diagnosis on the Surgical Treatment of Tumors of the Brain.
- Dr. Claude F. Dixon, Rochester, Minn.: Cancer: Its Curability; Acute Abdominal Disease.
- Dr. Morris Edward Davis, Chicago: Use and Abuse of Cesarean Section.
- Dr. Ole A. Nelson, Seattle: Aortography for Diagnosis of Renal and Abdominal Conditions; Cervicitis in Relation to Urinary Symptoms and Backache.
- Dr. William W. Swanson, Chicago: The Commonly Missed Pediatric Diagnosis.
- Dr. Harry C. Warren, San Francisco: Surgery versus Conservatism in the Treatment of Pulmonary Tuberculosis.
- Dr. Edward William Alton Ochsner, New Orleans: Conservative and Radical Treatment of Bronchiectasis; Peripheral Vascular Disease.
- Dr. William D. Stroud, Philadelphia: Etiology of Cardiovascular Disease; Coronary Diseases Including Angina Pectoris; Clinical Efficacy of Digitalis Preparations.
- Dr. Robert T. Legge, Berkeley, Calif.: Occupational Diseases and Their Relation to the Medical Profession; Carbon Monoxide Poisoning and Its Treatment.
- Dr. Donald C. Collins, Los Angeles: Value of Papaverine Hydrochloride in the Treatment of Postoperative Pulmonary Embolism.
- Dr. Clarence M. Hyland, Los Angeles: Value of Convalescent Serum in Acute Contagious Diseases.

Before the meeting Dr. Swanson and Dr. Davis presented a course of lectures on pediatrics and obstetrics, respectively, August 31 and September 1. Dr. Claude L. Shields, Salt Lake City, was chosen president-elect and Dr. Menzies J. Macfarlane, Cedar City, was installed as president. Vice presidents elected were Drs. Donald A. McGregor, St. George, Jennings G. Olson, Ogden, and Warren O. Christenson, Wellsville. Dr. David G. Edmunds, Salt Lake City, was made secretary for three years.

VERMONT

Society News—Dr. William Wayne Babcock, Philadelphia, addressed the Rutland County Medical Society at a meeting in Rutland July 13 on surgical conditions of the stomach.

State Medical Meeting at St. Johnsbury—The one hundred and twenty-fourth annual meeting of the Vermont State Medical Society will be held in St. Johnsbury at the Vermont State Armory, October 13-15. A symposium on "Practical Surgery for the General Practitioner" will be presented by the following, all of the faculty of Temple University School of Medicine, Philadelphia: Drs. William Wayne Babcock, William A. Steel, Wilbur Emory Burnett, John Royal Moore and William Edward Chamberlain. Other speakers will be:

- Dr. Roscoe G. Leland, Chicago: Director, Bureau of Medical Economics; American Medical Association: A Challenge to Medicine.
- Dr. Walter Schiller, Vienna and New York: Early Diagnosis of Cancer of the Cervix Uteri.
- Dr. Francis M. Rackemann, Boston: Practical Points in the Diagnosis of Asthma and Hay Fever.
- Dr. William G. Ricker, St. Johnsbury: The presidential address: Modern Ideas in Diagnosis and Treatment as Exemplified by Hippocrates.
- Dr. Waldo J. Upton, Burlington: vice presidential address: Cerebral Arteriosclerosis.
- Dr. Christopher C. Shan, Bellows Falls: Agranulocytic Angina.
- Dr. DeC. Forest Jarvis, Barre: Clinical Experiences with Nondiabetic Use of Three Unit Doses of Insulin.

The sound film "Syphilis," produced by the American Medical Association and the U. S. Public Health Service, will be shown Thursday afternoon, October 14, at the Star Theater. The annual banquet will be held Thursday evening at the St. Johnsbury House, with Dr. Frank E. Farmer, St. Johnsbury, presiding.

VIRGINIA

Pediatric Clinician Resigns—Dr. Jay M. Arena, who has been the field clinician in pediatrics conducting graduate courses under the auspices of the department of clinical and medical education of the Medical Society of Virginia, has resigned to become associate professor of pediatrics at Duke University School of Medicine, Durham, N. C. Dr. Arena was graduated from Duke in 1932 and was associate in pediatrics on the faculty at the time of his appointment in Virginia late in 1936.

State Medical Meeting at Roanoke, October 12-14

The sixty-eighth annual session of the Medical Society of Virginia will be held in Roanoke, October 12-14, at the Hotel Patrick Henry. The meeting will open with clinics Tuesday afternoon conducted by Drs. Frank H. Lahey, Boston, on "Thyroids" and Winchell McK. Craig, Rochester, Minn., on "Surgical Treatment of Hypertension". They are the guests of the Roanoke Academy of Medicine. At the opening general session Tuesday evening Dr. James Morrison Hutcheson, Richmond, will give his presidential address and Dr. Russell L. Cecil, New York, will speak on "Pneumonia as a Public Health Problem". Dr. Thomas Parran, surgeon general, U. S. Public Health Service, Washington, D. C., will also be a guest, speaking on "The Part of the Practicing Physician in Syphilis Control". Among Virginia physicians who will participate in the program will be:

- Drs. James P. King and Frank A. Strickler, Radford: Insulin Shock; Treatment of Dementia Praecox.
- Dr. William B. Porter, Richmond: Nutritional Deficiencies and Their Relation to the Clinical Course of Heart Disease.
- Dr. James Asa Shield, Richmond: Fever, Malaria and Short Wave in Treatment of Neurosyphilis.
- Dr. Thomas D. Walker, Newport News: Determination of the Urinary Excretion of Ascorbic Acid (Vitamin C).
- Dr. Richard W. Garnett, Danville: Hospitalization by the Group Payment Plan on a Statewide Basis.
- Drs. Dudley C. Smith and Joseph M. Hitch, Charlottesville: Skin Manifestations in Tularemia.
- Drs. John S. Horsley, John S. Horsley Jr. and Guy W. Horley, Richmond: Improved Methods of Treatment for Appendicitis.

Wednesday afternoon there will be round table discussions of treatment of heart disease, obstetric problems, minor surgery, diarrhea, mental hygiene, treatment of trochanteric fractures of the femur by means of internal and external fixation, ray treatment of infection and treatment of nonvenereal urinary tract infections.

WISCONSIN

Special Meeting of the State Board—The Wisconsin State Board of Medical Examiners will hold a special meeting October 14 at the Hotel Witter, Wisconsin Rapids, for consideration of reciprocity applicants only. Dr. Henry J. Gramling, Milwaukee, is secretary of the board.

Society News—Drs. Everett D. Plass, Iowa City, and Hugh A. Cunningham, Milwaukee, will address the Medical Society of Milwaukee County, Milwaukee, October 8, on "Toxemias of Late Pregnancy" and "Obstetrical Anesthesia and Analgesia" respectively. Dr. Herman A. Heise, Milwaukee, will be the speaker for the special feature "Fifteen Minutes of Preventive Medicine," on "Bacterial Allergy."—Drs. Walter G. Sexton and Robert S. Baldwin, Marshfield, addressed the Green Lake-Wausara County Medical Society, Wautoma, August 12, on "Infections of the Urinary Tract" and "Diabetes Mellitus" respectively.

GENERAL

International Dermatologic Congress in New York—The tenth International Congress of Dermatology and Syphilology will be held in New York in September 1940, it is announced. Dr. Oliver S. Ormsby, Chicago, is president general of the congress and Dr. Paul A. O'Leary, Rochester, Minn., secretary general.

Automobiles Kill 196—Deaths caused by automobiles in 125 major cities in the United States during the week ended September 18 totaled 196, six fewer than in the corresponding week of last year, according to the bureau of the census of the U. S. Department of Commerce. Los Angeles recorded the highest total with eighteen deaths, Chicago placed second with sixteen deaths and New York third with thirteen. Most of the cities reporting have a population of 100,000 or more, it was stated.

Annual Safety Congress in Kansas City—The twenty-sixth National Safety Congress and Exhibition will be held in Kansas City, Mo., October 5-8, at the Municipal Auditorium under the presidency of Dr. Cassius H. Watson, New York. Among physicians scheduled to participate in the program are:

- Dr. Harold A. Vonachen, Peoria, Ill.: Placement of Men from the Standpoint of Physical Fitness.
- Dr. Louis Schwartz, U. S. Public Health Service, New York: Industrial Dermatitis and Its Prevention.
- Dr. Richard D. Mudd, Saginaw, Mich.: Industrial Burns and Their Treatment.
- Dr. Hymen I. Spector, St. Louis: Industrial Tuberculosis—A Public Health Factor.
- Dr. Glen E. Kassebaum, El Dorado, Kan.: The Worker's Health.
- Dr. James R. Garner, Atlanta: Fatigue and Its Relation to Accident Prevention.
- Dr. Royd R. Sayers, U. S. Public Health Service, Washington, D. C.: What Industrial Dusts Are Hazardous? Why?
- Dr. Allen D. Lazenby, Baltimore: The Doctor's Part in Controlling Dust Hazards.

Dr Roy R Jones U S Public Health Service Washington, Metal Fume Poisoning and Its Prevention
Dr Peter B Rastello Detroit Electroplating Fumes and Vapors and Their Elimination

Clinical and Climatological Meeting—The fifty-fourth annual meeting of the American Clinical and Climatological Association will be held in Baltimore at the Belvedere Hotel, October 11-13. Among speakers on the program will be

Dr Francis M Rackemann Boston Molds as a Cause of Hay Fever and Asthma
Dr Alvin H Gordon Montreal The Mental Complications of Heart Disease
Dr Joseph T Wern, Cleveland Is Hypertrophy of Heart Muscle Beneficial?
Dr Stride D Blackford Charlottesville Va Similarities of Tuberculosis to Tuberculosis
Dr John H Musser, New Orleans Deficiency Disorders as Observed in the Far South
Drs Thomas M Rivers S M Ward and Robert D Baird New York Vaccination Against Smallpox by Means of Intradermal Inoculation of Cultured Vaccine Virus
Dr Henry Rawle Geyelin New York Treatment of Diabetes with Protamine Insulin

Dr Warfield T Longcope, Baltimore, will deliver the Gordon Wilson Lecture Tuesday at noon on "The Varieties of Hemorrhagic Nephritis and Their Prognostic Significance." At the annual dinner Tuesday evening Hon Morris A Soper, Baltimore, judge of the United States District Court, will be the speaker on "Medicine and the Law."

Southern Psychiatric Association—The annual meeting of the Southern Psychiatric Association will be held at the Gunter Hotel, San Antonio, Texas, October 8-9, under the presidency of Dr William D Partlow, Tuscaloosa, Ala. Dr William H Cade Jr, San Antonio, president, Beaver County Medical Society, will give the address of welcome, and speakers will include

Dr George T Harding Columbus Ohio Periodicity of the Manic Depressive Psychoses
Dr Giles W Day, Galveston Texas Newer Methods of Psychiatric Treatment
Dr Whitman C McConnell St Petersburg Fla Endocrinology in Psychiatry
Dr Guy F Witt Dallas Texas Mental Disturbances Due to Bromide Intoxication
Dr James A Willie Houston Texas Analysis of a Case of Hysteria
Dr Isham Kimbell Lexington Ky Necessity for Comparative Study of Schizophrenic and Organic Reaction Types of Psychoses
Dr Walter J Otis New Orleans, Childhood's Early Symptoms of Mental Hygiene Problems
Dr David Henry Poer Atlanta Ga Psychoses Due to Thyroid Disorders
Dr Philip Smith New York Psychiatric Work in New York Institutions
Dr C Charles Burlingame Hartford Conn Can the Point of View and Technique of Private Practice Be Carried into the Mental Hospital?
Dr George R Herrmann Galveston Neurocardiac and Neurocirculatory Disorders
Dr Witten B Russ San Antonio Psychoses Complicating Surgical Cases
Dr Newdigate M Owensby Atlanta Sanity in Psychiatry

American College of Surgeons—The twenty-seventh annual Clinical Congress of the American College of Surgeons will be held at the Stevens Hotel, Chicago, October 25-29, under the presidency of Dr Eugene H Pool, New York. In addition to clinics and demonstrations, the program includes symposiums on cancer, industrial medicine and traumatic surgery and fractures, and conferences on obstetrics and gynecology and on graduate training for surgery. Certain sessions will make up the annual hospital standardization conference. At the various evening sessions, the following speakers, among others, will present papers

Dr James H Means Boston Indications for Surgery in the Treatment of Peptic Ulcer
Dr Roscoe R Graham Toronto Technique of Surgical Treatment in the Treatment of Peptic Ulcer
Dr Howard C Naffziger San Francisco, Nucleus Pulposus and Lower Back and Sciatic Pains
Dr Dean Lewis Baltimore Relation of Chronic Cystic Mastitis to Cancer of the Breast
Dr Cecil K Drinker Boston, Genesis and Consequences of Lymphedema
Dr Willis D Gatch Indianapolis Circulatory and Lymphatic Disturbances in the Abdomen
Dr Claude F Dixon Rochester Minn Diverticula of the Intestine
Dr Henry W Cave New York Immediate or Delayed Treatment of Acute Cholecystitis (Liver Shock and Death)
Dr Frank Hinman San Francisco Tuberculosis of the Kidney
Dr John Mason Hundley Jr Baltimore Physiologic and Pathologic Changes in the Urinary Tract During Pregnancy
Dr Irvin Abell Louisville Ky President Elect American Medical Association Acute Pancreatitis

A feature of the presidential meeting and convocation Monday evening will be the annual college oration on surgery to be delivered by J P Lockhart-Mummery, M B, London, England, on "The Surgeon as a Biologist." Introduction of foreign guests will take place on this occasion. The oration on fractures will be presented Thursday evening by Dr William O Sherman, Pittsburgh, on "The Present Status of the Operative Treatment of Fractures."

Foreign Letters

LONDON

(From Our Regular Correspondent)

Sept 4, 1937

Annual Meeting of British Association for Advancement of Science

In his presidential address before the British Association for the Advancement of Science Sir Edward Poulton surveyed the controversy on evolution, which he had witnessed at the meetings of the association since the doctrine was first presented there fifty years ago. Although it was a relatively easy matter to establish that evolution occurs, the causes are extremely complex and even today are a matter of dispute. He supported Darwin's theory of natural selection. From his own experience as an entomologist he brought forward evidence incompatible with Lamarckian evolution. In the relation between predatory animal and victim there was commonly no opportunity for the latter to learn by means of experience. The elaborate adaptations by which sedentary insects remained hidden from their enemies were evolved not by contact but by avoidance of enemies. An example was the resemblance of certain caterpillars to twigs. They fed only by night and spent the day rigid, their attitude simulating a twig. Carrick had recently shown that this device completely deceives hungry birds. An example of "prophetic instinct" was found in the maggot of an African fly. It lived in soft mud which, during the dry season when the chrysalis stage was reached, would be traversed by deep cracks in which insectivorous birds could search. While the mud was still soft the maggot prepared for danger. By tunneling spirally up and down it made a line of weakness which caused a pillar to separate from the mass when the mud hardened and contracted. It then tunneled into the still soft pillar, where it became a chrysalis. However wide the cracks, the maggot had arranged that they would not involve the cylinder. This prophetic instinct could be explained only by the operation of natural selection.

An explanation of evolution different from both Lamarckism and Darwinism has been styled orthogenesis. It means evolution in a definite direction as the result of predetermined internal tendencies. But, as Dyer said in an address at a previous meeting of the association, this was like explaining the movement of a train by a tendency to locomotion. Darwin lifted the whole matter out of the field of mere transcendental speculation by the perfectly intelligible mechanism of natural selection.

In many quarters Mendelism was at first regarded as antagonistic to Darwinism. But the older belief that only large variations—mutations, as they were called—were subject to Mendelian inheritance, and that small variations were not inherited, disappeared by further investigations. The foundation of Darwinism thus became immensely strengthened.

Sir Edward Poulton ended his address by referring to "the greatest of the problems by which we are faced—the end of international war." The physiologist Michael Foster, in his address to the association in 1899, said that "happily the very greatness of the modern power of destruction is already becoming a bar to its use." Many looked on the great war and later wars as the end of Foster's dream of peace, but Sir Edward hoped that the association did not thus despair. He referred to the address of the paleontologist Sir Richard Owen, delivered in 1858, who in referring to the transatlantic cable said "We may confidently hope that this and other applications of pure science will tend to abolish wars over the whole earth." Confident words were inspired by the forging of a new link between the two great English speaking nations. Nearly eighty years had passed, but with all the terrible disappointments

there had been great progress. A time would surely come, and might it come quickly, which would prove that this dream was prophetic.

TESTS FOR COLOR BLINDNESS

In her presidential address to the Section of Psychology, Dr. Mary Collins discussed the tests in common use for the detection of color blindness. The most common and the most important form of color blindness was red-green. Recent figures gave the percentage of the population affected as from 5 to 12, in contrast with the older figure of from 3 to 4. Her own result was 7.5. The figures did not indicate that the defect is increasing but that detection is more accurate owing to improved tests. It is gradually being realized that there are many degrees of this defect. In extreme forms there was complete blindness to red and green, but in a milder form these colors could be discriminated if conditions were favorable, but when unfavorable, as in mist or fog, the colors were confused. Tests for color defects fell into two categories, in which transmitted and reflected light were respectively used. While the former was regarded as more fundamental, the latter could be of great service for quick diagnosis. As spectrometric examination was not always possible, the lantern or pigment test could be used as a substitute. Both were essential when lack of color discrimination involved risks to the community. Another category was that of persons with unequal sensibility to red and green. Some were "red weak," others "green weak." Difficulty of detection of color blindness was increased by the deliberate tricks practiced by affected persons to avoid detection. One man suffering from complete red-green color blindness was yet able to make passable copies of paintings. To obtain green he mixed blue and yellow but never used green paint, even though to normal eyes it might be an exact match.

SELF HYPNOTISM

Before the Section of Psychology Dr. William Brown, Wilde reader in mental philosophy and director of the institute of experimental psychology, University of Oxford, read a paper on "Hypnosis, Suggestibility and Progressive Relaxation." He said that, although it was true that persons of certain pathologic types were easily hypnotizable, relatively normal people were also hypnotizable to different degrees. In the hypnotized and relaxed state the statements made to the patient should always be positive in character. In this way not only might faulty mental function be rectified but mental powers, such as concentration and memory, might be increased above normal. Inhibitions, doubts, conflicts and fears of failure could be removed, and the power of imagination of success, which was of extraordinary importance in many of these cases, could be reinforced.

Almost anybody with care, deliberation and concentration could hypnotize himself. "You must concentrate your mind on a point of the far distant horizon. Relax your muscles completely and say to yourself 'I am getting drowsy.' While in this state you must make suggestions to yourself of increased powers—such as that you will have a good night's rest tonight, or you are going to make a speech tonight without stammering. You can do that without harm to yourself and with great benefit." Dr. Brown thought that, whatever opinions might be held with regard to the political aims of the totalitarian countries, their methods of attaining national efficiency under individual leadership found support in modern psychology.

THE SEX RATIO

For the subject of his presidential address to the Section of Zoology, Prof. F. A. E. Crewe took "the sex ratio," on which he commented mainly in relation to the human species. He said that the statistical review of the registrar general was one of the most interesting zoological papers to appear each

year, "as a progress report of a vast and exciting zoological experiment which we are conducting scientifically or otherwise, with ourselves as the experimental material." The primary sex ratio (the ratio at conception) was in this country about 120 males to 100 females, but as the males were more delicate at all ages the numbers became equal in late adolescence, and in maturity the females outnumbered the males, until at the age of 85 and over women were more than twice as numerous as men. Professor Crewe believed that the greater delicacy of the male was an instance of a general principle applicable to the male of all organisms and was due to the male having a higher rate of metabolism, which made him less resistant to unfavorable conditions. The sex ratio at birth was "an instrument of precision by which a human society may measure the quality of its structure," a yardstick to determine the success of social services and health measures. The equality of the sexes in early maturity he regarded as brought about by adaptive adjustment of the primary sex ratio and differential sex mortality to give equal numbers of males and females at the optimal period for reproduction. The precise sex ratio of a species must not be regarded as a biologic accident but as a delicate adjustment of contrary forces brought about by selection during the course of gestation.

In the discussion, Dr. Walton of Cambridge reviewed the possible methods by which the sex ratio could be experimentally controlled. In mammals the most promising line of attack was to find some means of separating the male determining from the female-determining sperms. This was theoretically possible and might be of enormous economic importance in stock breeding and might open new vistas in economic biology.

PARIS

Sept 4, 1937

International Congress for the Protection of Children

The twelfth International Congress for the Protection of Children was held in Paris, July 19-21 inclusive, with the secretary of public health, Mr. Mark Rucard, presiding. The work of the congress was taken up in four sections. In the medical section the first paper was by Drs. Lesne and Huber of Paris on the diet for children of school age as agreed on by the majority of foreign and French pediatricians. This was 100 calories on the average per hundred kilograms and a well balanced ration including from 55 to 60 per cent of carbohydrates, 30 per cent of fats and 15 per cent of proteins. Dr. Koenen of the Netherlands called attention to the danger of underfeeding due to unemployment and the necessity of teaching the proper preparation and utilization of foods. Grulee of Chicago emphasized the existence of the individual factor and the need of vitamins. Messerli of Switzerland showed the close relation between adequate feeding and resistance to infection. Rickets and hypotrophy are at present increasing in frequency, a direct result of unemployment and underfeeding. Veras of Greece stated that in countries bordering on the Mediterranean a great deal of bread is eaten. Meat is replaced by fish, butter by oil. Vegetables and fruit are plentiful. The subject of convulsions in infancy was discussed by a number of speakers. There was general agreement that the syndrome may be due to a number of different causes and that the prognosis was not favorable from the psychic and neurogenic points of view. About 60 per cent of epileptic persons give a history of convulsions in infancy, according to Dr. Babonniere, who was particularly pessimistic as to the future of children who have had convulsions in infancy. The treatment must be both symptomatic and causal. The most frequent causes are obstetric trauma, heredo-alcoholism, hereditary syphilis and encephalopathies due to a not yet identified virus, often latent until the convulsions appear.

The pedagogic section discussed the legitimacy, effects and mode of application of punishment. Corporal chastisement ought never to be used after the age of 7. Punishment is not only legitimate but necessary in order to arouse a sense of judgment, of self criticism and of social duty in children. Punishment should be judiciously stimulating and never create an inferiority complex in the child. At school, as at home, an effort should be made to arouse the spiritual value of being good and a sense of responsibility.

In the legal section there was general agreement with regard to the great value of juvenile courts. These were established in France in 1935. Their objectives should be both penal and educative under surveillance as wards of the courts. The influence of the cinema was favorably commented on, but surveillance was deemed indispensable for children.

In the social section, Dr Devraigne called attention to the widespread existence of inadequate housing in France. Eighteen per cent of the families have only one room, and in the larger cities 26 per cent of the homes are occupied by too many persons. Ten per cent of these 26 per cent have one room for three persons, 33.7 per cent one room for from five to seven persons, and 40 per cent one room for seven persons. This overcrowding is responsible for physical, social and moral defections.

Congress of Medicine as Applied to Physical Education and Sports

The first International Congress of Medicine as applied to Physical Education and Sports was held in Paris July 11-17. Many representatives of foreign countries took part in the program. The necessity of medical surveillance of physical education in childhood and adolescence was the subject of many of the papers. Examination of the heart in its reaction to effort was discussed by Laubry of France, and Van Boggaert and Brouha of Belgium. A study of the fatigue or obstacle reaction test of respiratory capacity was reported by Donaggio of Italy. The necessity of close cooperation of the teacher, physical instructor, parents and physician was emphasized in papers read by Oelsnitz of France and Giovanni of Italy. Demonstrations were given by pupils of the Irene Popard and Susanne Lenglen schools of Paris and by members of the officers' physical culture center near Paris.

Meeting of French Orthopedic Congress

The president of this year's French Orthopedic Congress, which will be held in Paris, October 7-9, will be Prof Etienne Sorrel. The first day will be devoted to clinics at various Parisian hospitals. At the second day's session, papers will be read by Drs Leveuf and Perrot on tendon transplantations on the foot for infantile paralysis, and by Dr Allard of Berck on bilateral coxalgia. The third day will be spent at clinics in Parisian hospitals and on the day following the close of the congress the members will visit the various orthopedic institutions at Berck-Plage in the North of France, one of the largest centers for the treatment of tuberculous bone lesions in the world. Those wishing to attend this congress should write to Dr Andre Richard, 45 Avenue Paul Doumer, Paris (16) or Dr Louis Tavernier, 7 rue de Bonnel, Lyons, France.

Study of Action of Morphine on Kidney

In a graduation thesis by Claude Macrez, which appeared recently, the results are given of experiments which show that in large doses morphine checks diuresis and the selective action of the kidney on the blood, but that this action is only temporary and does not cause any changes in the renal parenchyma. Repeated subcutaneous daily injections over a period of several months of one-sixth grain (0.01 Gm) or more are not followed by any progressive increase in the blood urea content or by microscopic changes in the kidney. Hence morphine can be given without hesitation in heart disease, even if generalized edema or a high blood urea content exists.

Silver Nitrate Solution for Instillation in Eyes of New-Born

At a recent meeting of the Academie de medecine a report was submitted by a special committee, headed by Professor Tiffenau, which had been appointed to study a modification of the present 2 per cent silver nitrate solution, which obstetricians and midwives are obliged by law to use as a prophylactic against ophthalmia neonatorum. The committee in its report recommended a reduction to a 1 per cent solution, as the instillation of a 2 per cent solution, when more than one drop was used, had been followed by corneal ulcerations. With the weaker (1 per cent) solution, the use of from 2 to 4 drops was found to be perfectly safe. The report of the committee was adopted.

Course in Broncho-Esophagoscopy by Dr Chevalier Jackson

Dr Chevalier Jackson of Philadelphia has been invited by Dr J M Le Mee to give a course in broncho esophagoscopy at the Fanny Blumenthal Clinic in the Children's Hospital of Paris. The course will begin September 1 and end September 10. The number of participants is limited to twelve. The clinical lessons will be given in Dr Le Mee's service and work on the cadaver at one of the dissecting rooms of the medical school.

Report of Studies on Progressive Muscular Atrophy

The Italian clinician Professor Meldolesi of Rome recently reported to the Berlin Medical Society on his investigation of progressive muscular atrophy. His material comprised more than 100 cases and covers a period of nine years. Especially characteristic features of the clinical picture are the progressivity, a typical muscular deficiency which pervades all the musculature, even the apparently unaltered, characteristic disturbances of metabolism, a familial diathesis, and a disturbed digestion. The most frequently exercised muscles are the first to be affected, and if strenuous exertion has been customary the course of the disease will be particularly severe. The muscle substance becomes as pale as fish-flesh as a consequence of myoglobulin deficiency. The muscular metabolism is always disturbed in that, whereas much creatine is secreted, the elimination is reduced. This disorder, like the always demonstrable disturbances in sugar metabolism (reduction of the glycogen control of the musculature) results from disturbed myoglobulin metabolism. Myoglobulin is a catalyzer of carbon dioxide and the basis of the serum and hence inhibits acidosis of the working muscle which would otherwise ensue. The disappearance of myoglobulin produces all the other clinical signs of progressive muscular atrophy. Meldolesi was likewise able to detect in the healthy relatives of myopathic patients the presence of myoglobulin deficiency together with its sequels, such as the increased excretion of mesobilirubin, a decomposition product of myoglobulin, in the bile and in stools, creatinuria, and depletion of the glycogen reserves of the musculature. This myopathic diathesis was observed by Meldolesi in sixty families. Myoglobulin deficiency is a character transmitted from the accessory chromosome through the female sex. In all cases in which the myopathic diathesis led to disease, the pancreas was found to be much altered anatomically and functionally. External pancreatic secretion was always influenced and the ferment values, especially of trypsin, were notably reduced. The extent of this hypochylia paralleled the severity of the general disturbance. The anatomic substratum of this alteration was a pancreatic sclerosis. According to the metabolic tests undertaken by Meldolesi, the myopathic patient presents a state of deprivation in which the protein reserves are com-

pletely exhausted. In this state absorption fails in the myoglobin deficient muscle fibers, further damaged by exertion. If a person who presents the myopathic diathesis sustains a pancreatic injury, he will fall prey to progressive muscular atrophy. As a therapeutic measure Meldolesi administers large doses of pancreatic substance. According to his observations, within six months this treatment will reestablish the protein balance and arrest the progress of the disease. In severe cases, orthopedic operations can be of great benefit just as in poliomyelitis. For the improvement of muscular metabolism, Meldolesi administers intravenous injections of dextrose and insulin.

Influence of Depth and Type of Respiration on Basal Metabolism in Lungs

The influence of respiratory depth and type on the basal metabolism in the lungs is best viewed from the standpoint of energetics. In addition, the size of the dead space is an important consideration. The literature contains considerable divergence of opinion as to whether the effective dead space of the respiratory tract is greatly altered by the deepening of respiration. There are two opposing schools of thought. Haldane and his followers on the one hand assume that deepened respiration produces marked enlargement of the dead space, whereas Krogh and his associates found that increased depth of respiration effects a relatively low grade enlargement of the dead space. Recently F. Grosse-Brockhoff, assistant to Professor Rein in the Bonn medical clinic, carried on studies of the dead space at the physiologic institute of Gottingen University. He was aided in this investigation by Schoedel. Grosse-Brockhoff reported the following results before the Bonn Medical Society. It should be kept in mind that the proper withdrawal and measurement of the alveolar air is the predominant factor in determining the size of the dead space and also that in the method of obtaining this air lies the greatest possibility of error. The first experiments concerned estimates of the alveolar air based on the method of Benzinger and Bruch. The following data were elicited. As respiration is deepened the dead space undergoes a pronounced increase, for example, from 150 cc during a respiratory depth of 500 cc to 750 cc during a respiratory depth of 2,800 cc. These observations correspond throughout with those of Haldane, yet a previous theoretical evaluation of the fluctuation of the alveolar air in the expiratory phase rendered questionable the accuracy of the mentioned experimental results. It then became necessary to apply a method that would permit a series of any number of inspirations to be analyzed in particular phases. In this manner a true mean value of the "expiratory alveolar air" could be obtained. On the basis of this procedure the investigators reached the following conclusions. If a person is in repose and the respiration deepened, the dead space exhibits only a slight increase. And if the person is active the dead space will generally be even smaller than when the person is in repose. This phenomenon is to be explained by the fact that the size of the effective dead space is dependent on the type of respiration and on the velocity of the air current in the respiratory passages. Measured in terms of carbon dioxide, the dead spaces are usually smaller than if measured in terms of oxygen. This observation verifies the assumption that parts of the lungs can function as respiratory epithelium for easily diffused carbon dioxide, whereas the same areas play no part in the oxygen exchange. The variations in the alveolar air are also of interest on other grounds. It is clearly demonstrable that between depth of respiration, type of respiration and middle position of respiration on the one hand and the extent of alveolar air on the other there exist interrelations which under certain circumstances must also influence the variations of the oxygen saturation in the blood. It may also be expected that in short and rapid respiration with lowered middle position the oxygen saturation in the blood is subject to marked variations. In such pathologic states

oxygen therapy ought to exert a most favorable influence, as by its use the partial pressure necessary for saturation of the blood will remain adequate at the end of the expiratory phase.

Investigation of Bee Venom and Serpent Venom

Similarities between bee venom and serpent venom have already been time and again attested on a physiologic basis. Recently Drs. Tetsch and K. Wolff carried on experiments at the Pharmacologic Institute of Berlin University to establish chemically analogous substances within the two poisons. Both chemical and biologic procedures were followed. Bee venom can be kept in physiologic solution of sodium chloride for an indefinite period. Fairly important variations in toxicity based on the source of the poison and the season may be observed. The mean value of the minimal lethal dose is approximately 100 micrograms per gram of body weight of a mouse. Nonpoisonous fractions can be obtained from bee venom in an aqueous solution by extraction with ether and chloroform. Histamine is rendered precipitable by trimetaphenol and a powerful toxic substance is found in the precipitate. It is interesting to note that sulfur, too, is present in bee venom.

The venom of the rattlesnake *Crotalus terrificus* was then tested. Here extraction of the protein regularly leads to detoxication. Dialysis was ineffectual. On the basis of the analyses it can be concluded that bee venom, crotalin and cobra venom are all protein substances. Biologic tests of isolated intestines of guinea-pigs also evidence the similar composition of crotalin and bee venom. Both the natural poisons and the picrate fractions separated therefrom produce the same "tachyphylactic" effect in the intestine.

BUENOS AIRES

Sept. 1, 1937

American Trypanosomiasis

Dr. S. Mazza reported on studies made in the laboratories of the Mission de Estudios de Patologia regional of Buenos Aires University at Jujuy (*Prensa med. argent.* 24:1394 [July] 1937). In the last two years he observed 240 cases of acute forms of Chagas disease with a mortality of 58 per cent. Cases have been reported from the littoral, northern, central and western zones of the country, including regions with a temperate climate. Chagas' erroneous statement that trypanosomiasis produces goiter was a hindrance to the studies. Patients suffering from trypanosomiasis do not develop goiter if they live in nongoitrous zones of the country. In goitrous zones the patients suffering from goiter or from endemic cretinism do not develop trypanosomiasis. The presence of edema of the eyelids and sometimes general edema, adenopathies and hepatosplenomegaly are all signs of diagnostic value. Some children die with meningo-encephalitic symptoms. Mothers' milk may contain trypanosomes. The latter can be inoculated through the skin by scratching and also through the ocular conjunctiva. Scratching causes the infection by inoculating the feces of *Triatoma*. Mazza states that in all countries of South, Central and North America acute trypanosomiasis will be found, especially in children, if extensive researches are made. Dr. Dios and his collaborators reported results of studies on triatomas in Argentina which were carried on at the Instituto Bacteriologico of the National Department of Hygiene (*Folia biologica* 1937, Nos. 70-73). The researches were begun in 1915 by Maggio and Rosenbusch and have been carried on for twenty-two years. Examination of 30,865 insects showed that from 15 to 25 per cent of the insects are infected in the northern and central areas of the country, from 10 to 15 per cent in the western areas and 11 per cent in the Rio Negro toward the south, where it is cold. If Argentina, a large part of which enjoys a temperate climate, has so high an index of triatoma infestation, the index must be higher in the tropical regions of South, Central and North America.

Antituberculosis Center

The Argentine League Against Tuberculosis gave orders for the beginning of the construction of a large center for the study and treatment of tuberculosis. The building for the center is being constructed on a lot of 90,000 square meters given by the municipal authorities of the city to the league. The cost of the construction will be 5,500,000 Argentine pesos (about

Antituberculosis center under construction in Buenos Aires

\$2,750,000) Donations from the people of Argentina have amounted to \$300,000. The House of Deputies has already allowed \$1,500,000 and will give the remainder of the cost on completion of the building.

Institute of Surgery

The work on the construction of an institute for postgraduate medical and surgical studies at the ward of clinical surgery of Prof. M. Jorge at the Durand Hospital has been advanced, and an amount of \$1,500,000 is to be expended in the construction.

New Faculty of Medicine

The laying of the corner stone of the new faculty of medicine of Buenos Aires took place August 9. There will be two buildings, each having ten stories in the front and eighteen stories in the rear.

VIENNA

(From Our Regular Correspondent)

Aug. 8, 1937

The First International Short Wave Congress

Immediately following the second Congress of the Austrian Society of Roentgenology, July 12, the first International Short Wave Congress convened in Vienna. Four hundred members were present. The proceedings were conducted in three sections, on physics, medicine and biology, which met simultaneously. The administrative organization of the entire congress was entrusted to the Viennese docent Dr. Liebesny. As presidents of the sections were chosen Professor Dr. Arsonval of Paris, Senator Marconi of Rome, who has since died, and Professor Zeunek of Munich. The federal government of Austria and the municipal government of Vienna welcomed the assembled scientists in the usual ceremonious way. An extraordinary historical collection of all kinds of apparatus and machines in some way related to the production, utilization and investigation of short waves was on exhibit at the Viennese Technical Museum and aroused the interest of the delegates and the public as well.

Dr. Schliephake, a pioneer of short wave therapy, designated, as the main fields of short wave therapy, suppurative-inflammatory diseases of the skin, of the nasal sinuses and of the pleura and the lungs. Only moderate dosage is helpful, overdosage can be most harmful and underdosage is ineffectual. Professor Maragliano of Genoa recommends short wave therapy in joint diseases, both acute and chronic (arthritis deformans), especially in combination with roentgen therapy.

Professor Wintz of Erlangen has obtained favorable results from the use of short waves in acute gynecologic inflammations. He irradiates the patient with minute doses or else applies larger doses to the ovaries in order to reduce the function of those

organs. It was elicited in the discussion that mastitis likewise responds favorably to this therapy. Similar results have been reported in Germany, Denmark, Hungary and America. On the basis of the literature one may expect much from short wave therapy. It was repeatedly emphasized that only low intensity doses ought to be applied, especially in acute conditions, in order to maintain a so called athermic or minimal heating effect.

Professors Scheminzky of Vienna and Schliephake of Giessen and Dr. Patzold of Erlangen discussed the effect of short waves on living cells according as the tissue is exposed to the influence in the coil induction field, ray field or condenser field. Dr. Dalton of London was able to adduce proof of the specific thermal effects produced by short electric vibrations. Professor Jellinek of Vienna has found that the microscopically visible cellular alterations differ from those usually caused by electrical influences.

Dr. Liebesny provided a historical account of our knowledge of short waves. Fifty years ago, Hertz discovered the waves which have been named for him. Arsonval, Marconi and Zeunek developed Hertz's discovery. Subsequent development of the field was done largely by three Viennese scientists: von Lieben, who invented the cathode ray relay in 1905, and Eugen Reisz and Siegmund Strauss, who constructed the first electronic tubes in 1911. In 1924 the condenser field was first made use of by Schereschewski in Boston. In 1929 Schliephake first applied short waves for therapeutic purposes.

Other papers submitted to the medical section were concerned with the use of short waves in varied diseases. Acute infectious infantile paralysis has been treated by short waves by Colarizi of Rome. Whereas the Italian claims to have achieved favorable results, Wolf of New York, who conducted experiments with monkeys, has been less successful. Dr. Merdinger of Rumania believes that favorable results should be anticipated only if the treatment has been begun in the early stages of the disease. It is chiefly the Italians who have made use of short wave therapy in all conceivable conditions, including chronic appendicitis, and inflammation of the eye and skin.

Samuels of Amsterdam has favorably influenced disturbances of the endocrine system by means of short waves. Ruete of Marburg applies this therapy, to the exclusion of other measures, in suppurative processes of the skin. He has in particular been able to bring about remissions in the much dreaded furunculoses of the upper lip and nose. He also recommends this treatment in scleroderma.

Raab of Charlottenburg described experiments on the influence of short waves on the gonads and on fetal development. He found that short waves if not administered in excessive doses exercise no perceptible permanent influence on the developing embryo and that the aggregate of hereditary characters is in no way impaired. In plant embryos, however, Roth of Vienna observed a marked reaction to short waves, which was manifested in part by retardation, in part by acceleration of the period of germination.

Liebesny of Vienna stressed the need for the avoidance of heat effects in the application of short waves. Electric currents of all types possess a specific electrical effect on living tissue, which is independent of the thermal effects. The latter are above all to be avoided in the short wave treatment of inflammatory tuberculosis. Liebesny and Pace exhibited a film in which they demonstrated how powerful short wave dosage disturbs the normal arrangement of fluid atoms in milk, and liquid fat. Krasny-Ergen of Stockholm has undertaken similar investigations and is in accord with Liebesny. These two reports are of the greatest import with respect to the theoretical foundation for the practical claims of low intensity applications.

Krausz of Poland strongly recommended the use of short waves in trachoma and in suppurative injuries to the eyes and after ocular operations and infections.

Wolf of New York made some interesting observations on the effect exerted by short waves on the circulatory system whereas mild doses dilate the capillaries and thus cause the arteries to supply greater quantities of blood, large doses damage the capillaries and at the same time dilate the arteries, thus inducing consecutive hyperemias in the tissue under treatment. Weissenberg of Vienna has found also that resistance of the skin to electricity is increased by mild irradiation but reduced by larger dosage.

Lux of Vienna stated that he had observed that in the short wave therapy of furunculosis, certain furuncles become absorbed by the organism and this motivates the formation of antitoxins. In this way furunculoses of years' duration are frequently brought to speedy cure. On the basis of this observation Lux has treated more than 100 cases of chronic rheumatism which presented purulent foci in the region of the teeth (oral sepsis) by systematic dental irradiation with short waves. Lux believes that by this procedure antibodies against the toxins of rheumatism are formed and that this makes possible the preservation of the teeth.

Marriages

RODERIC ORLANDO JONES, Elyria, Ohio, to Miss Margaret Carolyn Moore, of Norfolk, Va, in Durham, N C, June 9

ELIJAH EUGENE MENEFEE JR, Lynchburg, Va, to Miss Eleanor Chittenden of Weldon, N C, June 5

CHARLES EDWIN MCNAMARA, Washington, D C, to Miss Virginia Adams of Lynchburg, Va, June 16

WILBUR CURTIS HUNSUCKER, Gibson, N C, to Miss Helen Marie McKown at Blackston, S C, July 5

ENMETT T ACKERMAN, Gays Mills, Wis, to Miss Georgia Florence Gilbert of Madison, September 1

WILLIAM G KRUCKENBERG, Lowden, Iowa, to Miss Lenore Clinch of Elgin, Ill, in Chicago, July 3

VESEY MARKLIN JOHNSON to Miss Lois Ruth McCortney, both of West Palm Beach, Fla, June 1

JOHN PAUL MCCLOSKEY, Johnstown, Pa, to Miss Pauline Isabel Fisher of South Fork, June 28

ANTHONY C MARGLIANO, Joliet, Ill, to Miss Marcella Marguerite Coyne, in Chicago, July 15

ROBERT J W KINZEL, Battle Creek, Mich, to Miss Marjory Jane Hall of Indianapolis, July 3

LAWRENCE J KEENAN, Fond du Lac, Wis, to Miss Helen Pfister of Sheboygan, August 7

DWIGHT C WIRTZ to Miss Dorothy Edwards, both of Des Moines, Iowa, September 4

EVERETT IRVING BUGG JR, to Miss Annie Laurie Newsom, both of Durham, N C, in June

ROBERT G DIESS, Sharpsburg, Pa, to Miss Cornelia A Chilcote of Pittsburgh, June 30

CHARLES HOUSTON GAY to Miss Mary Irvine Carter, both of Martinsburg, W Va, June 29

FORNEY L MURRAY, Bristow, Okla, to Miss Edith Caroline Larson at Joplin, Mo, in June

JAMES LLOYD MASSEY to Miss Mary McGeehee Wyatt, both of Birmingham, Ala, June 30

PAUL SHEETS PENTECOST, Liberty, Ind, to Miss Martha Shock of Richmond, June 26

CHARLES ZURAWSKI, Providence, R I, to Miss Irene Webber of Trenary, Mich, June 30

WILLIAM R ARTHUR, Hampton, Iowa, to Miss Julia M Edick of Eldora, July 22

PAUL THURLOW PETIT to Miss Mary Sue Stone, both of Charleston, S C, in July

CHARLES H BEHNKE, Oshkosh, Wis, to Miss Dorothy Panay of Milwaukee, August 9

MAURICE A MICHAEL to Miss Esther Simon Armon, both of Philadelphia, June 20

SAMUEL McLANAHAN, Baltimore, to Miss Evelyn Willoughby Sharp, July 2

URBAN J DURNER to Miss Alma Radtke, both of Milwaukee, July 29

SAMUEL MILLER, Akron, Ohio, to Miss Esther Holter, June 28

Deaths

Jacob Diner, New York, Fordham University School of Medicine, New York, 1913, member of the Medical Society of the State of New York, formerly dean of the College of Pharmacy of Fordham University, and professor of pharmacology, toxicology, materia medica and clinical diagnosis at his alma mater, at one time member of the Committee of Revision of the U S Pharmacopeia, on the medical advisory board during the World War, past president of the New York State Pharmaceutical Association and the New York Academy of Pharmacy, was attending clinical microscopist at the Fordham Hospital, visiting physician and consulting pathologist to the Knickerbocker Hospital, New York, consulting physician to St Mary's Hospital, Hoboken, N J, aged 66, died, July 25, in a sanitarium at Amityville, L I, of chronic endocarditis and cerebral hemorrhage.

James Alexander MacMillan, Detroit, University of Toronto Faculty of Medicine, Toronto, Ont, 1893, member of the Michigan State Medical Society, fellow of the American College of Surgeons, past president of the Wayne County Medical Society, emeritus professor of proctology at the Wayne University College of Medicine, formerly known as the Detroit College of Medicine and Surgery, surgeon to the Providence Hospital, consulting surgeon to the Eloise (Mich) Hospital and the Receiving Hospital, for many years division surgeon for the Pennsylvania Railroad, aged 73, died, July 5, at his summer home in Kingsville, Ont, Canada.

John Francis Dowling, Hartford, Conn, Long Island College Hospital, Brooklyn, 1890, member and formerly vice president of the Connecticut State Medical Society, past president of the Hartford County Medical Society, formerly member and president of the city board of health, president emeritus of the medical staff of St Francis Hospital, on the consulting staffs of the Hartford Hospital, Mount Sinai Hospital, Municipal Hospital and the Bristol (Conn) Hospital, aged 81, died, July 20, of arteriosclerosis, heart disease and shock due to a fall.

John Campbell Spencer, Palo Alto, Calif, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1885, member of the California Medical Association and the American Urological Association, past president of the San Francisco County Medical Society, at one time associate professor of genito-urinary surgery at the University of California Medical School, San Francisco, formerly mayor of Palo Alto, served during the World War, aged 76, died, July 4.

Henry J Farbach of Louisville, Ky, Hospital College of Medicine, 1907, member of the American Urological Association, at one time professor of histology and bacteriology at the Louisville and Hospital Medical College, for many years on the staffs of the City Hospital and the Methodist Episcopal Deaconess Hospital, aged 56, died, July 6, in the Eitel Hospital, Minneapolis, of heart disease, while attending the meeting of the American Urological Association.

Guy Shearman Peterkin, Seattle, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1895, member of the House of Delegates of the American Medical Association in 1909 and in 1915, member of the Washington State Medical Association, North Pacific Surgical Association, and the American Urological Association, fellow of the American College of Surgeons, aged 65, died, July 22, of a self-inflicted bullet wound.

Edward Milton Overton, Bay Shore, N Y, University and Bellevue Hospital Medical College, New York, 1915, fellow of the American College of Surgeons, attending surgeon to the Southside Hospital, Bayshore, consulting surgeon Mather Memorial Hospital, Port Jefferson, Brunswick General Hospital, Amityville, and Suffolk Sanatorium, Holtsville, aged 55, died, July 10, at Orlando, Fla, of coronary thrombosis.

Miner Raymond Kendall, Cleveland, Western Reserve University School of Medicine, Cleveland, 1914, member of the Ohio State Medical Association and the American Academy of Ophthalmology and Oto-Laryngology, otologist for the board of education, served during the World War, on the staff of the U S Marine Hospital, aged 49, died, July 13, in the Lakeside Hospital of cirrhosis of the liver.

William C Ford, Woodstock, Va, College of Physicians and Surgeons, Baltimore, 1896, member of the Medical Society of Virginia, past president of the Shenandoah County Medical Society, secretary of the county board of health, for many years county coroner, member of the county school board and town council, aged 71, died, July 8, of carcinoma of the stomach with metastases.

Hervey Williams Whitaker ☉ Columbus, Ohio, Starling Medical College, Columbus, 1881, formerly professor of rhinology and laryngology at his alma mater, served during the World War, at one time member of the board of trustees of the public library, for many years on the staff of the Children's Hospital, aged 79, died, July 12, of injuries received in a fall

Hugh Stanley Douglas, Toronto, Ont, Canada, University of Toronto Faculty of Medicine, 1923, member of the Associated Anesthetists of the United States and Canada, served during the World War, junior demonstrator in anesthetics at his alma mater, on the staffs of the Hospital for Sick Children and St Michael's Hospital, aged 41, died, July 10

Thomas Mulligan ☉ Grand Forks, N D, University of Toronto Faculty of Medicine, Toronto, Ont, Canada, 1904, past president of the North Dakota State Medical Association, fellow of the American College of Surgeons, member of the surgical staffs of the Grand Forks, Deaconess, and St Michael's hospitals, aged 60, died, July 19, of heart disease

Jamie William Dickie ☉ Southern Pines, N C, Jefferson Medical College of Philadelphia, 1918, formerly secretary of the Moore County Medical Society, served during the World War, fellow of the American College of Physicians, medical director and superintendent of the Pine-Crest Manor Sanatorium, aged 43, died, July 6, of pneumonia

Earl Vinton McComb ☉ Menominee Mich, Northwestern University Medical School, Chicago, 1907, past president and secretary of the Menominee County Medical Society, served during the World War, formerly city health officer, on the staff of St Joseph's Hospital, aged 53, died, July 6, of coronary thrombosis

Alva Archillous West ☉ Guthrie, Okla, Sioux City (Iowa) College of Medicine 1897, Northwestern University Medical School, Chicago, 1906, past president of the Logan County Medical Society, aged 64, on the staff of the Cimarron Valley Wesley Hospital, where he died, July 4, of cerebral hemorrhage

David W Gaddie, Hodgenville, Ky, University of Louisville Medical Department, 1884, member of the Kentucky State Medical Association, past president and secretary of the Larue County Medical Society, formerly county health officer, aged 75, died, July 12, of lymphatic leukemia

James Frank Smith, Leesville, La, Tulane University of Louisiana Medical Department, New Orleans, 1904, member of the Louisiana State Medical Society, past president of the Vernon Parish Medical Society, formerly parish coroner, aged 72, died, July 3, of carcinoma of the prostate

Ray Vaughan ☉ Cedar Mills, Ohio, Ohio Miami Medical College of the University of Cincinnati, 1913, past president of the Adams County Medical Society, aged 53, died, July 2, in the University Hospital, Columbus, of hypernephroma with metastases of the lungs

David Decker McNaughton, Argyle, Mich, University of Michigan Department of Medicine and Surgery, Ann Arbor, 1887, member of the Michigan State Medical Society, past president of the Sanilac County Medical Society, aged 71, died, July 6, of heart disease

Claude L Taylor ☉ Doylestown, Pa, Jefferson Medical College of Philadelphia, 1924, served during the World War, county medical examiner, aged 43, at one time assistant surgeon lieutenant, junior grade, U S Navy, was killed, July 11, in an airplane accident

Aileen Marjory Betteys Corbit, Oxford, Mich, University of Michigan Department of Medicine and Surgery, Ann Arbor, 1902, member of the Michigan State Medical Society, formerly village health officer, aged 59, died, July 12, of cerebral hemorrhage

William Cleveland Woodcock, Denver, Tulane University of Louisiana Medical Department, New Orleans, 1906, member of the Colorado State Medical Society, on the staff of the Denver General Hospital, aged 52, died, July 6, of pneumonia

William S Donnelly, Stillwater, N Y, Albany (N Y) Medical College, 1883, formerly chairman and member of the county board of supervisors, for many years health officer, aged 79, died, July 6, of chronic myocarditis and bronchopneumonia

Alfred Henry Stiebeling, Long Island City, N Y, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1883, aged 76, died, July 12, in the Grasslands Hospital, Valhalla, of an overdose of morphine

Edward Orestes Jenkins, Goodlettsville, Tenn, University of Nashville Medical Department, 1899, at one time state prison physician in Nashville, aged 60, died, July 7, in the Protestant Hospital, Nashville, of subdural hemorrhage

Fred Joseph Kraus, Chicago, Rush Medical College, Chicago, 1929, member of the Illinois State Medical Society, president of the staff of the Woodlawn Hospital, aged 37, died suddenly, July 11, of coronary thrombosis

George Wickliffe Webster, Providence, R I, Hahnemann Medical College and Hospital of Philadelphia, 1924, on the staff of the Homeopathic Hospital, aged 38, was shot and killed, July 16, by an unknown assassin

Hubert Felix Leach, Fort Worth, Texas, Fort Worth School of Medicine, 1899, for many years president of the board of trustees of the Weatherford (Texas) College, aged 61, died, July 4, of cerebral hemorrhage

Lanphear W Webb, Philadelphia, Hahnemann Medical College of Philadelphia, 1878, aged 70, died, July 12, in St Luke's and Children's Hospital, of injuries received in an automobile accident

Charles Riley, New Ross, Ind, Eclectic Medical Institute, Cincinnati, 1894, member of the Indiana State Medical Association, formerly county coroner, aged 70, died, July 12, of coronary occlusion

Charles Leone, Buffalo, University of Buffalo School of Medicine, 1911, member of the Medical Society of the State of New York, aged 52, died, July 4, of cerebral hemorrhage and hypertension

William Henry Seymour, Charles City, Iowa, Friedrich-Wilhelms-Universität Medizinische Fakultät, Berlin, Prussia, 1898, aged 71, died, July 4, in the Cedar Valley Hospital, of myocarditis

George Heywood Vernon, Beardstown, Ill, Hospital College of Medicine, Louisville, Ky, 1898, member of the Illinois State Medical Society, aged 62, died, July 6, of heart disease

Stephen Alvah Russell, Fairview, Mo, University of Tennessee Medical Department, Nashville, 1892, member of the Missouri State Medical Association, aged 67, died, July 2

James Timothy Marsden, Pueblo, Colo, University of the City of New York Medical Department, 1882, aged 82, died, July 6, in the Parkview Hospital, of pneumonia

Stanley F Wietrzynski, Chicago, Chicago College of Medicine and Surgery, 1914, served with the Polish Army during the World War, aged 46, was found dead, July 12

Woodman Robert Marriett, Capron, Ill, Rush Medical College, Chicago, 1886, aged 79, died, July 18, in the Municipal Hospital, Beloit, Wis, of prostatic hypertrophy

Lloyd Orrin Thompson, Greenwich, Conn, Dartmouth Medical School, Hanover, N H, 1893, aged 67, died, July 16, of chronic myocarditis and nephritis

Clifford Charles Porter, Greensburg, Pa, Jefferson Medical College of Philadelphia, 1888, aged 76, died, July 6, of erysipelas and pneumonia

Junius B Wright, Portland Ore, College of Physicians and Surgeons, Keokuk, Iowa, 1876, aged 102, died, June 20, of bronchitis and senility

George A Pruitt, Santa Cruz, Calif, Medical College of Ohio Cincinnati, 1877, aged 86, died, June 23, of heart disease and fracture of the hip

Samuel W Mims, Sylva, Ga, University of Georgia Medical Department, Augusta, 1878, aged 83, died, July 8, of coronary thrombosis

John Phillip Zieg, San Francisco, University of Michigan Department of Medicine and Surgery, Ann Arbor, 1896, aged 64, died, June 3

Frank P Young, Los Angeles, Kentucky School of Medicine, Louisville, 1893, aged 67, died, June 11, of arteriosclerotic heart disease

Rita Ehrmann Dunlevy, New York, New York Medical College and Hospital for Women, 1888, aged 73, died, July 6

Arthur Valentine Brown, Kitchener, Ont, Canada, Trinity Medical College, Toronto, 1904, aged 56, died, June 21

William Merrick Carn, Bowman, S C, Medical College of South Carolina, Charleston 1887, aged 74, died, June 28

George Buchanan, Toronto, Ont, Canada, University of Toronto Faculty of Medicine, 1871, aged 94, died, June 14

Kilpatrick Cross, Jacksonville, Fla, University of Georgia Medical Department, Augusta, 1910, aged 60, died, July 4

Ora Harland Cumberworth, Granger, Ohio, Starling Medical College, Columbus, 1901, aged 61, died, July 4

John E Wilkinson, Ottumwa, Iowa (licensed in Iowa in 1886), aged 100, died, June 28, of senility

Louis Robert Eichberg ☉ New York, Chicago Medical College, 1890, aged 67, died, July 6

should go with the recommendation for the treatment. I have had one case and that is all I am going to have until or unless the efficacy of the treatment and its essential harmlessness are more firmly established. I hope that the unpleasant effects may be modified or eliminated.

W D LUDLUM, MD, Brooklyn

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

CLIMATE IN ARTHRITIS

To the Editor—I have been confined to bed for the past nine months with osteo-arthritis of the spine. I have discontinued practice and sold my home with the idea of spending the summer in the north and then going to Florida to live in the fall. Is the climate of southern Florida suitable for a person who has arthritis or is the dampness injurious? My preference is for the west coast say at Fort Myers or Sarasota but I am told the humidity is marked, especially at night. Will you please advise me as to this?

E E EVANS MD Gary Ind

ANSWER—In general, patients with either atrophic (chronic infectious) arthritis or with hypertrophic (osteo-) arthritis feel better when they reside in a warm dry climate, hence Arizona and New Mexico are favorite states. Many arthritic patients have reported, however, that they were relieved of some of their symptoms by spending the winter in Florida or California, in spite of the humidity in these states. Unfortunately only a few formal studies have been made on the relationship of arthritic symptoms to the various climates in this country. The factor of barometric pressure is apparently more important to an arthritic patient than that of humidity, temperature or atmospheric electricity, according to Rentschler, Vanzant and Rowntree (*Arthritic Pain in Relation to Changes in Weather, THE JOURNAL*, June 15, 1929, p 1995), who studied the reactions of 367 patients with atrophic (not osteo-) arthritis to atmospheric and weather changes in Rochester, Minn., over the course of one year. Seventy-two per cent of the patients usually felt better when the barometer rose. However 21 per cent of the patients reacted in an opposite manner and had fewer symptoms when the barometer fell. In 7 per cent no relationship between symptoms and barometric changes was noted.

It was impossible to demonstrate any definite or consistent relationship between humidity and arthritic pains, and it was concluded that the factor of humidity alone was not important, although it may be important in conjunction with other factors. The same conclusion was reached regarding changes in temperature or in atmospheric electricity, between them and a patient's symptoms no general parallelisms were noted. Even those patients who were most consistently affected by weather changes did not react to them with complete uniformity. One "arthritic weather prophet," for example noted that changes in his symptoms paralleled changes in the curve of barometric pressure for about 77 per cent of the time that is, he felt better as the barometer rose, but for 20 per cent of the time the relationship was reversed and he felt worse when the barometer rose and better when it fell.

It would seem, therefore, that the advantages of a warm dry climate may be due not to a warm temperature or low humidity but to the evenness of the climate and temperature, and freedom from significant variations in barometric pressure. Regardless of humidity, therefore, states where climate is warm but where storms and changes in barometric pressure are frequent may be less suitable for the arthritic patient than states where the weather is colder but more "even." With these facts in mind, and realizing the variability and individuality of different arthritic patients to react to their environment, some arthritic patients may be distinctly pleased and note relief of symptoms in Florida in spite of the humidity and even in spite of storms and changes in barometric pressure. Others may feel no relief or may actually feel worse in spite of the warm temperatures.

It must not be forgotten that part of the relief which arthritic patients obtain during their visits to warm climates or to spas is undoubtedly due to the increased rest and relative freedom from worry and from traumatizing activity and to psychotherapy—"something is being done." Those who go to such places

and merely "lie in the sun" may be sadly disappointed, for a stay in a high dry climate may be advantageous in some cases, but not without the use of other forms of therapy. As one Tucson climatologist and student of rheumatism frankly stated "It must be understood that without the proper routine of living (a coordinated program of therapy) arthritis can continue as a sad and crippling disease even on the Arizona desert" (Holbrook W P. *Evaluation of Therapy in Chronic Atrophic Arthritis Ann Int Med* 7:457 [Oct.] 1933).

Incidentally, one point is not quite clear, why it is necessary for the patient with "osteo arthritis" of the spine to be confined to bed for nine months? Osteo arthritis (using the term not in the radiologic sense but in a clinical sense, a term synonymous with hypertrophic, degenerative or senescent arthritis) rarely if ever produces symptoms severe enough to confine a patient to bed for long periods. It may produce real pains or sciatica, but these symptoms are usually not severe enough to confine victims to bed for as long as nine months. Perhaps the patient is affected with the osteo-arthritic changes secondary to late or severe rheumatoid arthritis of the spine. A review of the diagnosis seems in order.

COBRA VENOM IN ARTHRITIS

To the Editor—Please give me information on the cobra venom treatment for arthritis? Where can I get it and is it of any real value?

E OSWALD VOYER MD Hollywood Calif

ANSWER—For a number of years various venoms, especially those of bees and snakes have been used in the treatment of a variety of diseases. Their virtues have been less impressive to physicians than to laymen, who have long favored ointments of snake oil and the stings of bees in the treatment of "rheumatism." Of commercial preparations of different venoms those of bees have been most widely used. Current sponsors of the use of bee venoms in the treatment of chronic arthritis and other rheumatic disorders are Beck, Mackenna and Baldermann.

In 1914 McCarty used crotalin snake venom in the treatment of several diseases including sciatica, no relief was obtained in the one case of sciatica so treated. Korbler reported an analgesic effect from the use of cobra toxin in one case of arthritis of a hip. Recently Macht commented on its analgesic effect in cases of tic douloureux, various neuralgias, chronic arthritis and other painful conditions not of malignant origin. According to Macht the analgesic action of cobra venom is much like that of morphine and other opium narcotics. A general discussion of the chemical constitution, physiologic effects and therapeutic application of snake venoms has been presented by Kellaway, by Kirschen and by Burkhardt.

It will be seen therefore that no extensive scientific study has been made concerning the value of cobra (or bee) toxins in chronic arthritis. Many believe that such relief as arthritic patients may obtain from bee or snake venoms is probably derived from a reaction somewhat similar to that from foreign proteins (milk, typhoid vaccine). The value of snake venom as a superior coagulant is more definitely established. Sterile solutions of snake venom (*Vipera russelli*) in dilutions of 1/10,000 or more are effective as local applications to stop bleeding in patients who have hemophilia with or without hemophilic arthritis. Others regard the venom of *Bothrops atrox* (fer-de-lance) cheaper, more available and more effective than Russell's viper venom.

The subject is discussed by the following authors:

CARBON TETRACHLORIDE POISONING

To the Editor—Can you supply me with any information on carbon tetrachloride gas poisoning, including symptoms and treatment?

EDGAR C SITES MD Port Huron Mich

ANSWER—Carbon tetrachloride may lead to at least three forms of poisoning for human beings (1) contact dermatitis, (2) asphyxiation, which is brought about only by gross exposures and resembles chloroform anesthesia, and (3) acute and subacute poisoning. As little as 100 parts of carbon tetrachloride vapors per million parts of air represents the threshold of beginning danger for those exposed. Davis has listed the following symptoms as characteristic of acute and subacute carbon tetrachloride poisoning: slight headache, nausea, nervousness, mental confusion, loss of weight, secondary anemia, slight jaundice, chronic spasms of the muscles, necrosis of the liver, acidosis, phosphaturia and irritative nephritis, loss of consciousness, coma, and in severe cases death, visual disturbances such as blurred vision, color confusion and disturbances of near vision.

The same author suggests the following with reference to treatment: removal from contact with the substance, aeration—fresh air, oxygenated if necessary, alkalization with sodium carbonate, calcium carbonate or intravenous calcium gluconate, ingestion of levulose, dextrose and animal fats, tincture of digitalis to protect the heart, hexylresorcinol for kidney irritation, intravenous administration of physiologic solution of sodium chloride and dextrose or Fischer's solution.

More extended information may be found in the following publications:

MANTOUX TEST IN TUBERCULOSIS

To the Editor—I have been told that there have been recently some reports that the Mantoux skin test has activated tuberculous lesions in children under 8 years of age. It has been my impression from reading the available literature that the Mantoux skin test, especially given with the purified protein derivative tuberculin in graded dosage, was absolutely without danger to any individual. Will you please let me have the best opinion on this matter as it affects the skin testing program in the primary schools?

MD Ohio

ANSWER—Observations made on many thousands of tuberculin tests administered by the Mantoux method have proved beyond doubt that the present standard dosage is without harm for both children and adults. When Koch's old tuberculin is employed, the first dose consists of 0.01 mg. Large numbers of workers use as the initial dose 0.1 mg. with no evidence of reactivation of previously existing tuberculosis. If there is no reaction to either of these initial doses it is still entirely safe to administer a full milligram. In fact, some workers use a milligram as the initial and only dose in their testing program and report no ill effects. Purified protein derivative has been employed in a two dose test (the dosage differs from old tuberculin but the directions accompany each package) on large numbers of children and adults with no harm whatever. In fact, its safety was carefully accurately and definitely determined before it was placed on the market. Already Long has prepared an intermediate single dose test of purified protein derivative which is also harmless.

In 1935 more than 1,124,363 tuberculin tests were administered through tuberculosis associations. It is probable that an equal number or even more tests were administered in the offices of physicians. These figures indicate the extensive use of the test.

Statements to the effect that the test has activated tuberculous lesions in children under 8 years may have any one of several sources. There are still physicians who confuse the intracutaneous tuberculin test of Mantoux with the old subcutaneous test. In the latter, large doses of tuberculin were administered that were sometimes capable of reactivating lesions.

It seems more probable that the source of the statements is an organization in this country devoting its entire time and effort to opposition of good health measures such as vaccination against smallpox, immunization against diphtheria, and the tuberculin test. Members of this organization are misinformed or malicious in intent. They make numerous statements that are false such for example as that the milk of cows which have had the tuberculin test is very dangerous for infants. In an attempt to alarm the public they cite cases in a most indefinite manner of persons who have lost their arms because of positive tuberculin reactions, they state that many children have become tuberculous and have died as a result of the tuberculin test. When one attempts to locate the cases so reported,

they are never to be found and usually no one in the community or even the family knows of the source of the tale. These persons attempt to leave the public with the impression that tuberculin contains living tubercle bacilli, when in reality whether it is Koch's old tuberculin or purified protein derivative it contains no tubercle bacilli either alive or dead.

On occasions, these persons have been known to distribute at the doorsteps pamphlets containing their propaganda just before a tuberculin testing program is to be initiated. This attempt to destroy the testing program may meet with a considerable degree of success. It usually reduces the percentage of consents for tuberculin testing of both children and adults. While it appears successful temporarily, it also creates intense interest in the tuberculin test, so that actual facts may be presented to an alert public.

Probably one thing did more to hasten the tuberculin testing program among cattle than the demonstrations by the opposition in a few states such as Iowa. The "cow testing war" rated headlines in many of the large daily newspapers and most papers carried some items concerning it. The absurd propaganda was exposed and the public convinced that it was definitely detrimental. Therefore the propaganda that is being disseminated in the correspondent's community if traced, will probably hasten the day when the test will be universally accepted.

ALOPECIA TOTALIS

To the Editor—A white woman aged 28 gives the following history. At 2 years of age she severely burned her right arm with hot coffee. She remembers that at the age of 4 there was an alopecia totalis but cannot recall how long prior to that time it existed. She was treated the next three years without results. Her mother was then advised by an Indian woman to apply tincture of iodine to the scalp. This was done every other day blistering the skin severely. Finally (time unknown) coarse bristles appeared over the scalp and eventually the hair became long. There was an area about the temples extending over the occipital protuberance on which the hair never regrew. Approximately eight years ago the patient suffered what was diagnosed as a nervous breakdown brought on by overwork. Since this was associated with a marked loss of hair she was advised to cut off the remainder. During this period she was treated by a specialist for eight months and under his supervision hair once more appeared. She was told however that she could never hope to retain her hair unless treatment was continued without interruption. This treatment consisted of local applications applied by the patient and some form of internal medication. Owing to financial conditions she was unable to continue under this regimen. The alopecia areata had never entirely cleared up even under this therapy. About three and a half years ago the patient married and almost immediately the hair began to fall out rapidly. A year and a half later she became pregnant and during the second month of gestation the hair came in all over the scalp even over the former bald spots. These hairs were fine and silky and the growth was heavy and long. After the child became 3½ months old every hair on the body fell out during a period of two days. Prior to this time she had such a heavy growth of hair on her legs that she was embarrassed when appearing in public in a bathing suit. At the time stated however scalp hair, eyelashes, eyebrows, axillary, pubic and body hair disappeared entirely and the patient began to gain weight and once more became exceedingly nervous. There was a marked pitting edema of both lower extremities. The menses had not yet made their reappearance. The basal metabolic rate was low, the Kahn test was negative and the blood count presented no variation from the normal. She was given desiccated thyroid internally and a maintenance dose of approximately 5 grains (0.3 Gm.) daily was established. Under this therapy she lost about 20 pounds (9 kg.) the edema disappeared and the menses recurred with normal rhythm. She has continued along this line for the past year and a half. There has been no local treatment. She has developed a scanty growth of hair in the axillary and pubic regions and a very fine almost imperceptible downy growth on the scalp. The eyebrows and eyelashes which are sparse at first were colorless but now they are becoming pigmented. Can you give any information as to etiology, further therapy and prognosis?

MD Illinois

ANSWER—The exact causation of alopecia totalis is not known. There are three popular theories as to its origin—the neuropathic, the parasitic, and the toxic—one or more factors being involved in the individual patient. In the case cited there is a definite history of nervous shock preceding the alopecia in childhood as well as the attack at 20 years of age. The regrowth of hair during pregnancy has been reported by Meacham (*Brit J Dermat* 24:272, 1912). The postpartum recurrence of the alopecia probably is due to an endocrine dysfunction. Sabouraud (*Ann de dermat et syph* 4:140, 1913) believes that alopecia areata is connected with hyperthyroidism and ovarian disease.

In this case, treatment must consist of local and internal medication. The local treatment consists of repeated blisterings of the scalp, using stimulating preparations such as alcohol, ether, tincture of iodine, phenol, resorcinol, tar, sulfur, mercurials, croton oil, cantharidal collodion, or 30 per cent chrysarobin either singly or in combination. Phototherapy has been used with good results by Finsen. Jersild, Ormsby, Fox and others. Internally, preparations of iron, quinine, cod liver oil, phosphorus, arsenic or strychnine are indicated in the patient's

general health is below par. Pilocarpine nitrate, from one-eighth to one fourth grain (0.008 to 0.016 Gm.) daily or pilocarpine hydrochloride, one eighth grain hypodermically have been used with success. Thyroid medication has given good results at times. Certain pituitary preparations have been used with varying degrees of success.

The prognosis varies with the age of the patient and with the extent of baldness. Relapses are frequent, but in young persons complete recovery usually occurs except in the universal cases. Ormsby states that "there is hope even when the downiest and thinnest growth can be appreciated." In alopecias of long standing in which there is atrophy of the hair follicles, the baldness may be permanent.

COATED TONGUE

To the Editor—I have had several patients complain of 'coated tongue'. In these patients there was no marked dehydration or prostration. Some were troubled with constipation and others were not. In the majority of those who were troubled with constipation, purging and laxatives had no effect on the condition of the tongue. Will you make some remarks about this? What would be a good remedy in cases in which no cause can be found?
M D Alabama

ANSWER—The condition of the dorsum of the tongue can be described as normal, coated, smooth (marginal or general), scrotal (smooth or coated), geographic or diseased. The term "coated tongue" describes an abnormal presence of terminal cells on the filiform papillae. These cells are usually degenerating.

The normal appearing tongue varies somewhat with the individual, the abnormal is caused wholly or in part by such factors as trauma (dentures), trophic causes, local disease (fungi, tuberculosis, syphilis), nutritional deviations (food, vitamins, fluids), systemic disease, upper and lower respiratory infections, oral sepsis, excess smoking, and the condition of the intestinal tract.

A British expression says that "the tongue reflects the condition of the gut," an expression which is incompletely true. It has been found that the condition of the mucosa of the tongue varies directly with the quantity of free acid in the gastric contents. Heavily coated tongues are often associated with hyperchlorhydria or normochlorhydria, the partly smooth (marginal) or bald tongues with hypochlorhydria or achlorhydria. (A notable exception is the coated tongue often accompanying a gastric neoplasm and its achlorhydria.) It is possible that another modifying, intrinsic, factor may be associated with the degree of chlorhydria.

Treatment of a possible cause is to be preferred to the use of such superficial methods as oxidizing ablutions, brushing or scraping. It is suggested that every effort be made to rule out constitutional, regional or local disease as a cause of coated tongue. A regulation of personal habits may be of help, as well as a sustained regulation of every apparent disorder of the gastro intestinal tract. To accomplish this a satisfactory fluid intake and an adequate food and vitamin ingestion are necessary. The most important aid to the entire tract may be a functional regulation, especially of the frequently occurring spastic colitis, by such means as a bland diet, sedatives, emollients, relaxation, and a regulation of bowel habit.

EPIDURAL INJECTIONS FOR PRIAPISM

To the Editor—In the January 23 issue of THE JOURNAL on page 322 the use of epidural injections for priapism is advised. I will appreciate your giving to me the technic of the procedure or advising me where it can be found.
M D California

ANSWER—The technic of epidural injections for priapism is exactly that followed by Valentine and Townsend for frequency of urination (*M Rec* 64 486 [Sept 26]). In cases of priapism 60 cc of physiologic solution of sodium chloride is injected and at times procaine hydrochloride is added to the saline solution in the proportion of 10 cc of procaine to 80 cc of saline solution. Cases treated by this method are reported by Hühner in the *Medical Journal and Record* (132 521 [Dec 3] 1930) under the title of 'Some Unusual Cases of Priapism'.

The technic as described by Valentine and Townsend is briefly as follows: "The patient may be placed on either side most comfortably on a table sufficiently high to render excessive stooping of the operator unnecessary. The skin over the sacrum is thoroughly scrubbed with green soap and water, then wiped with sterile pledgets of alcohol but not dried. In order to find the point of puncture, the left palm is pressed upon the sterilized skin, with the fingers well extended and held closely together. They are passed down the skin over the sacral spinous processes until the last perceptible one of these is felt under the pulps of the left index and middle fingers. These are then slightly separated and pushed down-

ward until each of them presses an osseous tubercle. The skin is firmly stretched with the same fingers over these tubercles, between them is the space to be punctured. The needle is taken between the right thumb and middle finger, the tip of the index-finger resting upon the attachment of the needle. So held, at an angle of about 40 degrees to the sacral curve, it is thrust through the space of skin tensely stretched by the left fingers. An instant later the right fingers receive the sensation that is imparted when an instrument is tested by means of tense drumhead. This is produced by the needle's point traversing the posterior-inferior sacral obliterating membrane. The shaft of the needle is then depressed about 20 degrees and the left middle fingers raised from the skin, and the left index is pressed upon the point of puncture to steady the needle and the tissues. In this position the needle is cautiously pushed up into the sacral canal. If each step of the technic has been sedulously followed, and no gross abnormality exists, the needle can be entirely inserted without touching the periosteum of any part of the sacral canal. The injection is made as follows: The left thumb and index-finger then firmly hold the needle's attachment, while the syringe is attached by the right hand. Nine tenths of the contents of the syringe are then slowly injected into the sacral canal without moving the needle. Then still slowly injecting, the needle is gradually withdrawn until its point is just beneath the skin. The last drop or two of the solution are then forced out, forming a little bulla at the point of insertion. If these precautions are carefully observed there will not be even a slight oozing of blood from the puncture."

TREATMENT OF SYPHILIS IN PREGNANCY

To the Editor—In the past seven years I have been treating a woman for syphilis. She has remained Wassermann fast. Two years ago I told her to become pregnant continuing treatment until term. I delivered her of a normal boy. The placenta, cord blood and maternal blood at this time were negative. I gave her two courses of neosarsphenamine and a bismuth compound following delivery. I gave up treatment because it seemed to me that her health was becoming impaired as a result of so much medication. She remained Wassermann negative. Her baby now is 17 months old. March 2 a Wassermann test on her was doubtful. She wants to have another baby. In view of the condition of her veins I have decided to let her have her way and give her eight ampules of bismuth arsphenamine sulfonate during each of her trimesters. Am I doing the right thing even if the next Wassermann reaction is positive?
M D Michigan

ANSWER—It would seem that the correspondent is on safe ground to permit another pregnancy. Not only is antisyphilitic treatment during the pregnancy probably not necessary but from the implied large amount of treatment that the patient has received it would probably be unwise.

SENILE ARTERIOSCLEROSIS AND BRAIN DEGENERATION

To the Editor—A man aged 72 who has never been seriously ill and has never had any operations during the past five years has slowly been developing a very unstable equilibrium. When he attempts to sit in a chair he misses the seat and sits on the arm or on the floor. He falls frequently with no apparent cause. He never has lost consciousness or presented any signs or symptoms that would simulate a cerebral accident of any kind. His voice is getting huskier and he reacts very slowly to questions. Although he seems to understand all questions asked it takes as long as five or ten minutes before he answers them. He is well oriented as to time, place and person. At times he thinks his relatives are against him and so he hides his wallet or other possessions. He cries easily. When told not to do something he does it when no one is looking. He laughs at times for no apparent reason. Examination is essentially negative. The blood pressure is 150 systolic, 80 diastolic. The pulse rate is 84. The urine and blood count are normal. The eye grounds are normal. He has a very good appetite but is slowly losing weight and strength. I have diagnosed the case as a depressed type of manic depressive psychosis probably on an arteriosclerotic basis. The patient is taking solution of potassium arsenite beginning with 2 drops three times a day and slowly increasing to 12 drops. Is there any further medication that might be used and is solution of potassium arsenite contraindicated?
J T HATTENBACH M D Lakewood Ohio

ANSWER—Both the mental and the somatic symptoms in this case are probably due to senile arteriosclerosis and brain degeneration. The speech difficulty and tendency to unmotivated laughing and crying may be a feature of so called pseudobulbar palsy caused by sclerotic changes in the brain stem. If the patient has not had any previous attacks of depression or mania, it is highly improbable that he now has a depressed type of manic-depressive psychosis. It is probably only a beginning ordinary senile psychosis. Both depression and delusions are common features. Small doses of solution of potassium arsenite will probably do no harm. It is not likely that any drug treatment will be of any avail except for the relief of symptoms as they arise. Theoretically vasodilators

such as iodides in small doses, should be beneficial, but experience with such drugs in senile mental disease has been disappointing

POSSIBLE RELATIONSHIP BETWEEN USE OF METALLIC SUBSTANCES AND X RAY SKIN

To the Editor—I am anxious to find out if there is any literature substantiating what seems to be a general belief among doctors that the metal salts will sometimes break down tissue previously exposed to too big dose or repeated x ray exposure. To present the question more clearly, I give a brief synopsis. X ray exposure of the hand occurred in December 1917. A slight dermatitis followed which healed in two or three weeks. Nov 30, 1918, eleven months after exposure the tissue of the hand broke down and sloughed severely after the hands had been washed in mercury bichloride solution excessively four or five days previous to the breakdown. Please give me any references that support the contention that mercury bichloride caused the sloughing.

M D Oklahoma

ANSWER—So-called x-ray skin often has a low toleration for insult or injury. Minor injuries may result in indolent ulcers. The application of any one of many chemicals in a strength sufficient to be an irritant may cause ulceration. This is more likely to occur when the application is in the form of an ointment. A strong solution of mercury bichloride might cause ulceration of such skin, simply because of the irritation and not because of any specific action of mercury. Excessive scrubbing with soap and water even might cause ulceration in some cases. The only literature on this subject with which we are familiar is contained in the standard textbooks, such as G M MacKee's X-Rays and Radium in the Treatment of Diseases of the Skin, G C Andrews' Diseases of the Skin, Otto Glasser's The Science of Radiology and Caldwell and Russ's X-Ray and Radium Injuries.

DETERMINATION OF STATUS OF SYPHILIS IN PATIENT

To the Editor—A man aged 26 would like to marry. After three years of uninterrupted treatment the Wassermann and Kahn reactions remain positive. His first Kahn test was found positive after a very thorough examination in which no physical defects of note were disclosed. At the hands of several physicians he has been given neosphenamine bismuth, arsphenamine sulfonate mapbarsen, yellow mercurous iodide, mercuric salicylate, mercury by inunction, potassium iodide by mouth, potassium bismuth tartrate, iodobismutol and hyperpyrexia treatments (five hours of 106.5 F body temperature repeated three times). At present he is having a rest period for the first time. The spinal fluid has never been tested. Will you kindly advise the course to be taken with this man? Should marriage be permitted?

M D Alabama

ANSWER—The patient has apparently been treated vigorously because of the persistently positive flocculation tests, but the data presented would indicate that no effort has been made to determine why the tests have remained positive. In other words, before endeavoring to determine the significance of the persistently positive blood tests it is necessary to determine the status of the syphilis. The spinal fluid should be examined by all means and a clinical search should be made for evidence of cardiovascular syphilis or signs of other visceral or mucous membrane syphilis. If the inquiry had included information as to the number of injections and the amounts of the various remedies given to this patient suggestions could be offered for the subsequent treatment. The patient should not marry until the status of the syphilis is determined by examination of the spinal fluid and the viscera.

DETERMINATION OF BLOOD CHEMISTRY

To the Editor—Kindly advise me as to what would be a low priced, fairly accurate apparatus for the determination of blood nonprotein nitrogen.

Roy G S DOUGALL M D Cobleskill N Y

ANSWER—There is no simple yet entirely satisfactory method of determining the different constituents of the blood. If any considerable amount of this work is to be done it would be advisable to follow the procedure that may be found in any good work on physiologic chemistry. Practical Physiological Chemistry by Hawk and Bergeim and Practical Physiological Chemistry by S W Cole contain clear descriptions of the methods. The equipment is not particularly expensive but the method is rather time consuming and requires a fair amount of chemical technique and a space that may be devoted to laboratory purposes.

Fairly accurate substitutes are offered in the form of fixed color standards with the appropriate equipment for preparing the blood supplied in convenient form. There are several such devices. The LaMotte apparatus made in this country and devices The Helige apparatus, made in Germany, seem to enjoy popularity. Any reliable scientific instrument dealer can supply prices and information concerning these devices.

GONADOTROPIC PRODUCTS

To the Editor—I have been treating cases of undescended testes with follutein at a cost of \$3 for each thousand rat units. Recently I have learned that antophysin, another anterior pituitary like product is obtainable at \$2 for a similar amount and 5 000 units of A P L (Ayerst McKenna and Harrison) may be obtained for \$6. As treatment for this condition is prolonged such a variance in price becomes a matter of importance. Will you kindly answer these questions: 1 Are antophysin follutein and A P L of equal potency and unit value? 2 Which are Council accepted? 3 Why such a marked difference in price?

M D New York

ANSWER—1 There are no known actual comparative assays of antophysin, antuitrin-S, follutein and A P L. So far as available data are concerned they are probably nearly equivalent, rat unit for rat unit, and the cheapest may be chosen.

2 None are as yet Council accepted but all are now under consideration.

3 All the products except A P L are licensed under a patent held by the manufacturers of antophysin. This probably accounts for the differences in price.

PURPURA IN PREGNANCY

To the Editor—Would chronic purpura haemorrhagica be an indication for the interruption of pregnancy? If so, what would be the best method for intervention? The patient who is 25, had a severe postpartum hemorrhage following spontaneous delivery of a living full term child fourteen months ago. This necessitated packing of the uterus, repeated transfusions and subcutaneous injections of snake venom. She was dangerously ill for a month. Would intervention now or labor be more dangerous from the standpoint of the mother's life? If pregnancy should be allowed to continue to term, what antepartum and postpartum precautions would you advise? Is subsequent sterilization of the patient indicated and if so what would be the best method?

M D New Jersey

ANSWER—Purpura haemorrhagica is always a treacherous condition when complicated by pregnancy. If the patient is in her first trimester the immediate interruption of pregnancy combined with sterilization will probably offer the best prognosis. This procedure should be carried out by abdominal hysterotomy in order that the sterilization may be performed at the same time. After midpregnancy the patient should be allowed to continue to term. A normal delivery can be awaited but in the event that conditions are ideal an elective low or cervical cesarean section and sterilization can be carried out under local anesthesia. Should normal delivery occur, sterilization can be carried out at a later date by laparotomy. A most important part of the treatment is that the patient receive a minimum of 500 cc of whole blood about twelve hours prior to an operative procedure. Should the patient go into labor, transfusion should be performed immediately. Preparations should be made for the treatment of postpartum hemorrhage in the event that normal delivery occurs.

PSEUDOICTERUS NOT DUE TO HENNA POISONING

To the Editor—I should like to obtain information on the subject of henna poisoning. I have under my care a woman of 34 whose chief complaint is excessive sweating. Among other pathologic conditions she presents yellow sclerae. The blood serum is intensely yellow, the icteric index by the acetone method is 20. The pigment is not bilirubin or carotene. There is no history of dimetrophenol ingestion. The patient has red hair and has used henna rinses for several years. A consultant has suggested the possibility of henna poisoning.

M D, New York

ANSWER—Henna is considered perfectly harmless. Should the hair dyeing have anything to do with the condition reported it would have to be due to some added chemical. Trinitrophenol (picric acid) is one substance that might be suspected as being the cause of the pseudo-icterus. If this is present in the system in considerable quantity, it can be detected in the urine in the form of picramic acid.

IRON AMMONIUM CITRATE IN ANEMIA

To the Editor—I would greatly appreciate any information you may give me regarding the use of iron ammonium citrate for the newborn anemic infant. I should like to know the correct dosage. Please omit name.

M D California

ANSWER—The following schedule of dosage of iron and ammonium citrate may be stated for infants and children:

Age 6 months	weight 15 pounds	0.10 Gm
Age 18 months,	weight 25 pounds	0.20 Gm
Age 3 years		0.30 Gm
Age 5 years		0.50 Gm

Even larger doses may be given in accordance with the modern tendency for large and liberal doses of iron medication.

West Virginia July Report

Dr Arthur E McClue, secretary, West Virginia Public Health Council, reports the oral and written examination held at Fairmont, July 12-14, 1937. The examination covered 11 subjects and included 110 questions. An average of 80 per cent was required to pass. Thirty-six candidates were examined, 35 of whom passed and one failed. Twenty physicians were licensed by reciprocity and one physician was licensed by endorsement. The following schools were represented:

Book Notices

Pediatric Dietetics By N Thomas Saxl MD FACP FAAP Associate and Lecturer in Diseases of Children New York Post Graduate Medical School Columbia University Foreword by Adolph G DeSanctis MD FAAP Director of Pediatrics at the New York Post Graduate Medical School and Hospital Columbia University New York Cloth Price \$7 Pp 565 with 59 illustrations Philadelphia Lea & Febiger 1937

While much has been written on infant feeding in concise handbooks and as a part of general textbooks on pediatrics, few books have presented the subject of pediatric dietetics separately in one volume. This book presents that material in a lucid and modern fashion. The volume is organized along three major divisions. In the first part of the book the author epitomizes the mechanics and chemistry of digestion during infancy and childhood, the various forms and types of food, their distribution, qualitative and quantitative compositions and how they are employed in the dietetic management of the infant and child. The roles of vitamins and minerals in metabolism are also concisely summarized. The second part of the book is concerned with infant feeding, both maternal and artificial. The third section considers the diet of infants and children in various diseases. Many specialists in their respective fields have collaborated with the author in this section. Finally, the appendix contains height and weight tables, recipes, general dietary suggestions, classified food tables, mineral and vitamin tables and a well selected bibliography to complement each section of the text. The book is well organized and carefully edited, and it is a storehouse of dietetic data useful in the everyday practice of pediatrics. The author has courageously considered the accepted proprietary foods in his discussion without bias. This has added to the value of his book. Certain special topics are not in keeping with the high quality of the rest of the book. The author should give this phase of his text more critical editing when the book is revised. In its present form, any physician will find this volume a useful addition to his medical library. It is comprehensive in scope, practical in its presentation and clearly and concisely stated. It reflects a sincere desire of the author and his collaborators to present the practicing physician with a useful source of data by which he may successfully meet the nutritional needs of the infant and child in health and in disease.

Maladies Infectieuses (deuxième série) Leçons cliniques professées à l'Hôpital Claude Bernard Par A Lemerle professeur à la Faculté de médecine de Paris Paper Price 55 francs Pp 309 with 15 illustrations Paris Masson & Cie 1937

This book contains seventeen clinical lectures based on cases illustrating various forms of infection. There are detailed, well planned lectures on cases of septicemia caused by the Pfeiffer bacillus, *B. proteus*, *B. perfringens* and *B. funduliformis*, on different kinds of ulceronecrotic pharyngostomatitis, on kala-azar, on malaria in Paris, on Hodgkin's disease with the undulant type of fever, and on other infectious manifestations. This is the second book by the author of clinical lectures on infectious diseases.

Common Skin Diseases By A C Roxburgh MA MD BCh Physician in Charge of the Skin Department and Lecturer on Diseases of the Skin St Bartholomew's Hospital London Fourth edition Cloth Price 15s Pp 401 with 173 illustrations London H K Lewis & Co Ltd 1937

This edition is characterized by numerous and excellent illustrations, an index of preliminary diagnoses grouped according to the essential lesions, suggestions for treatment in crystallized form which are proved and practical, and short, concrete, classic descriptions of the various diseases, all of which make for a vivid and noteworthy contribution to the General Practice Series. The book has been written for the general practitioner and the medical student, and the absence of numerous references and the inclusion of concrete suggestions for treatment should insure its popularity. Particularly worthy of favorable comment is the author's avoidance of lengthy discussions of the treatment of those dermatoses for which dermatologists have little to offer. The book is highly recommended to the medical student and the general practitioner, for whom it was written. Many dermatologists would do well to have it at hand for ready reference.

Lehrbuch der Nervenkrankheiten in 30 Vorlesungen Von Robert Bin-
ordentlicher Professor an der Universität Basel Fifth edition Paper
Price 25 marks Pp 618 with 207 illustrations Berlin & Vienna
Urban & Schwarzenberg 1937

The author continues the custom employed in his previous editions of presenting the subject matter in a series of thirty "lectures." The material is divided as follows: three chapters on diseases of the peripheral nerves, two on the dyskinesias, three on muscular dystrophies and atrophies, one each on multiple sclerosis and on diffuse diseases of the spinal cord, four chapters on syphilis of the central nervous system, one each on arteriosclerosis of the nervous system, on encephalomalacia and on aphasia, one chapter (of only thirty five pages) on tumors, inflammation and circulatory disturbances of the brain and the meninges, one on diseases of the cerebellum, two on congenital nervous diseases, two on "dysglandular syndromes," one chapter each on diseases of the vegetative nervous system and on epilepsy, three on the psychoneuroses, and one on the cephalalgias. Despite a certain prolixity of style, the author's presentation is generally clear and readable. Most of the data are competently handled, the chapters on diseases of the peripheral nerves, on the neuromuscular disorders and on aphasia are admirable. This edition, however, continues the two main defects of the previous ones: a dogmatic, oversimplified nosology and rather cursory and oftentimes incomplete sections on therapy. For example, the classification of brain tumors is didactically disposed of in two pages, whereas in discussing the treatment of dementia paralytica the author recommends fever therapy and mercury rubs but fails to mention either bismuth compounds or trypanamide. Perhaps the weakest portion of the work is that on the psychoneuroses, in which the author follows the classifications and the treatment of the preanalytic schools and excludes Freud, Jung and Adler even from the bibliography. In other respects the work is a fairly complete summary of the continental views on neurology and as such may be of interest to specialists in the field.

Baby Epicure Appetizing Dishes for Children and Invalids By Elena Gildersleeve Cloth Price \$1.75 Pp 141 New York E P Dutton & Co Inc 1937

The modern tendency in the feeding of infants and children is to broaden the diet to include a greater variety of foods. Nevertheless there seem to be more and more children who have to be made to eat. The cause may lie in failure to make the foods attractive. In this book, many dishes have been suggested that will do for the entire family and, particularly, will provide the child with a varied and wholesome diet. Dishes that call for the use of excessive amounts of sugar, starches, cream and butter have been omitted. Mothers and nurses who use the book will find it helpful in making meals attractive and aid in combating the problem of poor appetite in a child.

Hearing and Speech in Deaf Children By Phyllis M T Kerridge Medical Research Council Special Report Series No 221 Reports of the Hearing Committee V Paper Price 2s Pp 137 with 76 illustrations London His Majesty's Stationery Office 1937

It is estimated that there are about 40,000 persons deaf since infancy in Great Britain. Nearly 4,000 children of school age in England are deaf enough to require education in special schools. Of these, 500 in the schools of London were the object of the study the results of which constitute this report. The report shows that nearly one half of these children were born deaf, others became deaf on account of diseases that might be preventable. The majority of the children investigated were afflicted with a hearing defect before the age of 2 years. All gave evidence of some degree of mutism. Because of the extreme youth of those examined, the author overcame many obstacles in attempting to obtain an accurate estimate of the hearing loss presented by the children. There were experimental studies made with amplified sound which demonstrated not so much an improved faculty for hearing, as it resulted in improvement in speech of these afflicted children. Hence the use of amplified sounds is recommended to improve speech among such patients.

The reports will interest otologists because of the comparisons made of the results of hearing tests, new and old. The data on which determinations are based as to probable benefit of employing hearing aids for severely deafened children are

presented Those interested in pathology will find interesting clinical histories correlated with physical data For teachers of the deaf, the detailed reports of progress of a special group of forty eight children whose education was enhanced through the use of an electrical magnification sound apparatus will be interesting and suggestive The educational administrator will here find help in making estimates of the number of sound magnification instruments needed by schools for the deafened, if such afflicted children are to have the benefit of modern scientific advances Finally, even for the designer and manufacturer of hearing aids there are valuable data in the diagrams which indicate the severity and diversity of the physical characteristics of the ear

Psychiatric Social Service in a Children's Hospital Two Years of Service in Bobs Roberts Memorial Hospital for Children University of Chicago Clinics By Ruth M Cartland Assistant Professor School of Applied Social Sciences Western Reserve University Cloth Price \$1.25 Pp 105 Chicago University of Chicago Press 1937

This monograph records the experience of the Child Guidance Clinic of the Bobs Roberts Memorial Hospital of the University of Chicago Clinics The practical experiments described followed the recognition of the necessity for combined psychologic and pediatric knowledge and skill in the furtherance, growth and development of the child In the beginning an effort was made to have all patients referred to the psychiatric social worker, who could later arrange for the services of a psychologist and psychiatrist A few patients were referred directly from the outpatient clinic to the psychiatrist by physicians Service was established primarily to meet the needs of the pediatrician in the children's hospital Patients referred to it had been admitted either to the hospital or to its outpatient department The staff comprised a psychiatrist giving half time a psychologist giving half time and a psychiatric social worker giving half time, assisted by students in psychiatric social work

The purpose of the study was to determine the value of psychiatric social service in a children's hospital The children ranged in age up to 14 years The symptoms noted by the referring physician and thought by him to constitute reason for referring the child to the psychiatric service included habit disturbances, such as feeding, speech, enuresis, masturbation, night terrors, soiling constipation, thumb sucking, and nail and hand biting, introjective behavior such as restlessness, fears, timidity, seclusiveness, crying, day dreams, depression, apathy and slowness, illnesses unexplained by physical examination, and projective behavior such as school failure, mental retardation and overprotection by the mother The intelligence quotients by years and by sex indicate that the largest percentage of referred patients were in the range of average to dull The total number of treatment contacts over a two year period was 1,527, of which 926 were with parents and 601 with patients As told to pediatricians, parents brought children to the clinic because of physical symptoms only, physical symptoms associated with behavior, behavior only, school difficulties only, or speech defects Diagnosis consisted of a complete study of the child, physical, intellectual and social-emotional factors being coordinated Consultation service consisted of one or several interviews with the child, parent or agency social worker with a particular situation that did not seem to need full study Treatment consisted of continued work in the interest of the patient after physical, social, psychologic and psychiatric understanding revealed a capacity on the part of the patient or parent or both to utilize treatment

The author holds that a children's hospital seems to be a strategic place in which to render such service The records of the School of Social Service Administration are now being used for teaching and research It is implied that a psychiatric social service should be developed in many communities, but nothing is said about the cost of establishing and maintaining such a service Social service and the social worker are given prominent places throughout the report It is stated that 'social service and cooperation in any community are so dependent on the social self consciousness' of that community upon its attitudes that it is impossible to separate the two in our thinking"

Although this experience records some interesting observations, the results cannot be considered final or conclusive when based on such a small number of cases over a relatively short time

Ergebnisse und Fortschritte der Antimontherapie Von Prof Dr Phil Nat Hans Schmidt und Dr Med F M Peter Paper Price 15 50 marks Pp 218 with 8 illustrations Leipzig Georg Thieme 1937

This book aims to acquaint the reader with the achievements and the literature of the newer antimony therapy The main body of the book is taken up with abstracts of the enormously voluminous literature, arranged in as nearly logical clinical form as possible In this manner the authors "permit the reader to formulate his own conclusions," which it may be difficult for him to do in a number of instances on account of the reporting of directly opposite results It is obvious that antimony and potassium tartrate and the corresponding sodium salt have been superseded by organic compounds, among which experience has demonstrated a definite divergence of effects Thus the pentavalent antimony preparations are more effective in the treatment of kala-azar, while the trivalent are superior in the treatment of bilharziasis In helminthiasis and venereal lymphogranuloma the trivalent antimony is likewise the more efficient This determination is of great importance because with further development of these two classes of antimony derivatives the therapeutic effect becomes still further specialized Thus in the pentavalent neostibosan a specific against kala-azar has been developed, but the trypanocidal and spirocheticidal action that stibosan has is lost Among the trivalent antimonials the authors consider fuaadin to have achieved possibly the highest degree of specificity in its field As with arsenic, one has to distinguish between a "direct action" of the compound, such as is most especially responsible for anthelmintic action, from the "indirect action", i e, an effect on the system by which this is rendered capable of destroying the cause of the disease, when neither drug alone or the system alone could effect the cure Such action occurs in case of antimonial compounds in connection with the virus and bacterial diseases The newer antimonials must all be given parenterally, although with some of them intramuscular and subcutaneous administration is admissible The authors consider it remarkable that such a large number of diseases can be influenced by antimony, diseases the causes of which belong to such different groups of organisms as worms and protozoa, bacteria and filtrable viruses As a summary of what has thus far been done in this field and as an earnest as to what may be further accomplished, this book has an important place

La thyroïdectomie totale dans le traitement de l'insuffisance cardiaque et de l'angine de poitrine Par le Dr E Garcia Carrillo de la Faculté de médecine de Paris Paper Pp 159 Paris Maurice Lavigne Imprimeur 1937

This monograph contains a complete summary of the recent work done on total thyroidectomy in heart disease No new material is presented, but the author has given an excellent presentation of the development of this new surgical procedure of American origin To the reader in this country the book is superfluous, since the subject has been summarized many times in the various communications of Blumgart, Levine and others The appearance of the monograph at this time illustrates the lag in enthusiasm for new procedures in different countries In this country the operation is on the wane, but apparently in France the peak has not yet been reached

A Textbook of Embryology By Harvey Ernest Jordan A M Ph D Professor of Histology and Embryology University of Virginia and James Ernest Kindred M A Ph D Associate Professor of Histology and Embryology University of Virginia Third edition Cloth Price \$6 50 Pp 613 with 505 illustrations New York & London D Appleton-Century Company Incorporated 1937

The original plan of this volume, as stated by its authors, has not been changed since the first edition was published in 1926 In addition to the correction of errors present in the second edition, additions have been made under the topics of hematopoiesis, lymphatics, lung, sex determination, and anomalies These additions, however, are not at all extensive Comparison of the third with the first edition reveals the fact that surprisingly little new material has been added in the last eleven years This is the most serious criticism that can be directed against the latest edition of this book considering the advances that have been made in this field during the time Space for important new advances in embryology could perhaps have been made by the elimination of material of ques-

tionable value to the medical student or material more adequately dealt with in textbooks of other fields, for example, the chapter on eugenics. The brief discussions of anomalies appended to many of the chapters are a valuable feature of this work, although occasionally their interpretation might be questioned. For example, the consideration of hypernephroma as accessory suprarenal tissue invading the kidney is disputed by most pathologists and perhaps should not be included as an anomaly at all. The illustrations in the third edition are essentially unchanged since the first edition, they are numerous and generally clear but not otherwise noteworthy. This volume is a useful textbook for medical students and is more complete than most books of its kind in its field, but it falls short of bringing the subject down to the present.

Léčení diabetu [By] Dr. Otakar Postranecký [Therapy of Diabetes With Separate Diet Tables] Cloth Pp 158 Prague The Author 1937

This is a small volume designed primarily as a guide for the treatment of diabetes for the general practitioner. It is a fairly complete summary of the practical treatment of diabetes illustrated by many examples of patients and diets. It is arranged primarily for local use and as such it should serve as a guide for the man in general practice. It is not as critical a study as a similar volume which came from Prague in 1932 from a group of younger men from Professor Pelnar's clinic and it does not conform altogether with the ideas in this country. The chapters on coma and complications are well written. The impression given, however, is one of a somewhat unnecessarily involved management of the patient.

A Handbook on Diseases of Children Including Dietetics, Welfare and the Common Fevers By Bruce Williamson M.D. M.R.C.P. Physician to the Royal Northern Hospital London Second edition Fabrikhold Price \$4 Pp 329 with 62 illustrations Baltimore William Wood & Co 1936

This handbook will probably win the favor of the student as well as of the practitioner. In it are condensed the important phases of pediatric practice. It is thoroughly scientific, and accuracy has not been sacrificed in an effort to save space. Each disease is completely discussed, including a short statement concerning the treatment. A chapter on the formulary is included. In this revision certain chapters have been rewritten in accordance with the recent advances in pediatrics.

Handbook of Microscopical Technique for Workers in Animal and Plant Tissues Edited by C. E. McClung Ph.D. Professor of Zoology and Director Zoological Laboratory University of Pennsylvania Second edition Cloth Price \$8 Pp 698 with 82 illustrations New York Paul B. Hoeber Inc., 1937

This book, not being cyclopedic in aim, exhibits the advantages and the faults of a series of essays written by thirty-four authors on a subject that is still more art than science. It begins with an eight-page discussion of methods written for beginners by the editor. The chapter on the study of fresh material (ninety-one pages) includes an admirable account of the aims and procedures of microdissection. Twenty-three pages are devoted to the staining of bacteria, ninety pages to botanic methods, and here is the only discussion of hypoid techniques. Cytologic methods cover twenty-four pages, embryologic method thirty-three pages. The chapters on hematology (forty-five pages) include physical, chemical and histologic methods for the study of blood and blood-forming organs. Fifty-eight pages are given to bone and teeth, thirty-five to connective tissue and muscle, 185 to the central nervous system, thirty to the Protozoa. There is a general consideration of the effects of fixatives on living tissue and a chapter on staining which lacks any real understanding of the theory of staining but includes a comprehensive list of stains, their synonymy and some of their uses. A final chapter entitled "miscellaneous" includes methods of illumination for fresh study and microincineration, with an excellent though brief discussion of microchemical theory and one on fluorescent microscopy. Deficiencies in the work are: 1. Lack of an adequate discussion of the microtome knife and the sharpening of it. 2. Absence of an account of the celloidin methods by one of the many who regard these as the only adequate section methods. 3. No mention of any sense organs, although the outmoded "silver in the block" methods are given much space and space has even

been taken for pictures showing an author's idea of the correct arrangement of reagent dishes on the table and shelves. 4. The discussion of fixation by perfusion is defective because the author is not aware of the errors involved in washing out the blood with saline solutions and of the danger of using strong fixatives. He does not refer to the fundamental observations of Sauer on the effects of delay in fixing embryos. In the account of the Golgi apparatus, the theoretically important work of Owens and Bensley is omitted.

Evaluation of the Industrial Hygiene Problems of a State By J. J. Bloomfield and Mary F. Peyton Junior Chemist United States Public Health Service Prepared by direction of the Surgeon General U. S. Treasury Department Public Health Service Public Health Bulletin No. 236 Paper Price 15 cents Pp 126 Washington D. C. Supt. of Doc. Government Printing Office 1937

A somewhat detailed study of one fifth of the gainful workers in the state of Maryland shows that nearly all these workers were "exposed" to some sort of harmful material. There is no very clear definition of exposure. "With reference to medical facilities, this survey revealed that 31 per cent of the employees had the services of a full time medical practitioner and 42 per cent a part time physician. A first aid room was available to 56 per cent of the employees, while trained first aid workers were available to 65 per cent of the workers. There was practically no part time nursing service, but, on the other hand, 40 per cent of the workers were provided with full time nurses. The information on disability statistics showed that nearly half of the workers were members of sick benefit associations, while sickness records were kept for approximately 55 per cent of the employees." Perhaps the most valuable section of the report is the appendix on material for a reference library, which constitutes an extensive bibliography to sources of information on industrial hygiene.

Der einfache Schleimhautkatarrh der oberen Luftwege und seine Behandlung Von Professor Dr. Arthur Thost Mit einem Anhang Die Beschwerden der Sanger Schauspieler und Redner Paper Price 6.60 marks Pp 130 Berlin Julius Springer 1937

This is a rather lengthy work featuring in great detail the diseases of the upper respiratory tract with a special portion devoted particularly to singers, actors and public speakers. There is much that is of value in this work, with a considerable amount that in this country at least would not be considered important. The various medicaments, oils, sprays and mineral waters, it is now felt, do not have the importance in therapy they once possessed. Nevertheless, the specialist and even the general practitioner wishing a complete discussion of catarrh of the nose and throat may get it from this monograph.

Feeding Our Children A Simple and Understandable Exposition of the Principles of Nutrition Together with Their Practical Application to the Task of Planning Meals for the Various Ages By Frank Howard Richardson A.B. M.D. F.A.C.P. Cloth Price \$1 Pp 159 New York Thomas Y. Crowell Company 1937

Books on the feeding of children are myriad. Whether they are read by mothers who need the knowledge they contain is questionable. While the present volume contains essential information concerning the principles of nutrition and the practical planning of diets, it is of such length that it possibly may not fill the need for which it is intended. If a child becomes ill, his feeding should be carefully supervised by the physician. A few simple rules should suffice for the planning of the normal daily diet. Those mothers who are interested in the subject of child nutrition often become unnecessarily concerned about the matter of planning the child's diet. The book, however, is well written and simple enough so that it is easily understood. Those mothers who read it probably will find their efforts well expended.

Over zweren in maag en duodenum bij Inheemschen en Chinezen in Nederlandsch Indië Door Raden Soeharto Proefschrift ter verkrijging van den graad van doctor in de geneeskunde aan de geneeskundige hogeschool te Batavia [Ulcers of Stomach and Duodenum in Natives and Chinese in Netherland Indies Thesis for Doctor's Degree at Batavia Medical School] Paper Pp 93 Batavia C. Druk G. Kolff & Co [n. d.]

The author reviews the Dutch Indian literature on gastric and duodenal ulcers and discusses their frequency as demonstrated at necropsy and as diagnosed clinically in the medical

and surgical sections of the hospital at Batavia. He describes the anatomically and presumably etiologically abnormal types of ulcer and the other inflammatory changes of the gastric mucosa. Necropsies and clinical observations show that Chinese males have ten times as many gastric ulcers as the Malays and that gastric ulcer predominates over duodenal ulcers. The opposite is true for the Malays, in whom the etiology of the ulcers varies greatly and differs from the common type, not infrequently being of tuberculous origin. This thesis is only of local interest.

E. Merck's Jahresbericht Über Neuerungen auf den Gebieten der Pharmakotherapie und Pharmazie 50 Jahrgang 1936 Paper Pp 430 with 10 illustrations Darmstadt J. Merck 1937

The 1936 issue of Merck's Jahresberichte is its fiftieth anniversary. Professor Heubner's short preface portrays with great exactness the spirit of the entire enterprise of Merck as a firm, scientific research institution and literary review exchange of pharmacotherapy and pharmacy. There is one article on modern methods of drug and pharmaceutical analysis which discusses microchemical procedures. That this review appears from the control laboratory of E. Merck, Darmstadt, proves Merck's far-sighted leadership in the pharmaceutical field. The description of a new class of drugs, namely, the derivatives of coumarin-3-carboxylic acid, is especially well done. Also valuable is a pharmacologic investigation of European official and unofficial herbs. The Jahresberichte are most valuable for pharmaceutical control and research institutions and should be in the libraries of all educational centers.

Everyday First Aid By Walter Frank Cobb M.D. Medical Examiner Department of Hygiene College of the City of New York Cloth Price \$1.50 Pp 269 with 25 illustrations New York & London D. Appleton Century Company Incorporated 1937

Too frequently writers of books on first aid have erred in attempting to give too much information. This volume is different. It is unique in its manner of presentation. The reader is given an actual case to "aid," through the news report at the beginning of each chapter. In a way, each chapter is a "practice lesson" on what to do. The simple line drawings are helpful and well chosen to illustrate each lesson. The author does not indulge in moralizing to gain his objective but rather by skilful analysis leads his readers to think along the correct lines of first aid. Using the three letters of the word AID as key letters, the author states that all problems require the same technic. Thus, AID becomes "Ask—Inspect—Do." Emphasis is placed on practice. The physician can conscientiously recommend this book as an excellent addition to family libraries.

Heart Failure By Arthur M. Fishberg M.D. Associate in Medicine Mount Sinai Hospital New York City Cloth Price \$8.50 Pp 788 with 25 illustrations Philadelphia Lea & Febiger 1937

This book is intended primarily, the preface states, for the general practitioner. It discusses in considerable detail the newer investigations and theories concerned with adequate and failing circulation. The methods of determining the state of the circulation by clinical and laboratory means are extensively described. Since it is always helpful to understand the physiologic process causing a particular clinical picture, this volume should be of great value to practicing physicians. Because of its length and extensive citations of original authorities it probably will be found more useful as a reference book than as one that will be read from cover to cover.

Over het elimineeren van darmgassen storend voor de röntgendiagnostiek Door Linslo Willem van der Burg officier van gezondheid bij het Koninklijk Nederlandsch Indisch Leger Proefschrift ter verkrijging van den graad van doctor in de geneeskunde aan de geneesindige hogeschool te Batavia [Elimination of Intestinal Gases Which Interfere with Roentgen Diagnosis Thesis for Obtaining Doctor's Degree at Medical School of Batavia] Paper Pp 102 with 12 illustrations Brandoeng Java N. V. Maatschappij Vorkink 1937

The author describes the physiology and pathology of the digestive tract in relation to intestinal gases, the general preparation of the patient and the cleaning of the digestive tract, as prescribed in the literature. He discusses critically the current views described and proposes a personal method to eliminate the disturbing gases. It is wrong to let the patient

fast on the morning of the roentgen examination or to use charcoal preparations to absorb the gases. Castor oil, he believes, is superior to all other laxatives, the cleansing enema should be given with the patient lying on the right side and the roentgen examination should take place immediately after the enema has acted, the patient remaining on his right side until the moment of examination. Various drawings and copies of roentgenograms illustrate this interesting thesis.

Notes on Clinical Laboratory Methods Standing Committee on Laboratory Methods University of Glasgow Third edition Cloth Pp 86 with 6 illustrations Glasgow John Smith & Son Ltd 1936

This book covers only simple laboratory procedures used in "side room testing." It includes routine blood, urine, sputum and feces analyses and a few important special chemical tests. Although all the necessary information concerning these tests is included, it is not always clearly presented. Moreover, American medical students and technicians will find the book of little value, since it is specifically for Glasgow hospitals and many of the methods described are rarely used in this country.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Malpractice Limitation of Actions, Accrual of Right of Action—The plaintiff suffered from "malignant destructive myopia," threatening practical blindness in her right eye. The defendant, a physician, performed an operation on that eye, Jan 9, 1930, consisting, in the words of the defendant, of "what we call needling, breaking the capsule which holds the lens, breaking into the capsule and breaking up the lens to some extent so that the water in the anterior chamber is absorbed into the lens, causes the lens to soften and absorb and disappear." The vision in that eye seemed thereafter to have improved temporarily and a similar operation was performed on the left eye on May 11, 1930. The right eye, however, began to grow worse again, it appearing that after a lens has been removed the posterior capsule frequently becomes opaque, making it necessary to needle it also. Accordingly, the defendant performed a second operation on the right eye on May 9, 1931. Inflammation developed, which made necessary still another operation, May 11, 1931. Finally, in July 1931 the right eye had to be enucleated. The patient, Aug 8, 1932, brought an action in trespass to recover damages for the injuries to the eye and its ultimate loss. She did not claim that either the original or any subsequent operation was ill advised or was negligently performed. The action was for false and fraudulent representations, based on the allegation that the defendant had assured her that the operation was not a serious one and that it would correct her vision and would enable her to dispense with glasses. The trial court entered judgment for the defendant and the patient appealed to the Supreme Court of Pennsylvania.

The only question presented on appeal was whether or not the action was barred by the statute of limitations which required that it be brought within two years from the time when the "injury was done." The physician contended that the "injury was done" at the time of the first operation, Jan 9, 1930, and that therefore the two year period had elapsed before the suit was instituted. The plaintiff, on the other hand, contended that the statute began to run when the second operation was performed, May 9, 1931. The statute begins to run, said the Supreme Court, at the time the injury was done even though the damage may not then be known and may not in fact have occurred until afterward. Whatever injury was done to the plaintiff in the present case was occasioned by the first operation from which her condition on May 9, 1931, was a direct outgrowth. The secondary or capsular cataract removed at that time would not have occurred but for the operation on the lens. The patient contended that she could not know the

original operation was unsuccessful until the later measures proved unavailing and therefore the statute should not be held to run until that time. This argument, answered the Supreme Court, rested on a misapprehension of the nature of the present action. The suit was not based on a promise or guaranty that the plaintiff would be cured, the alleged fraudulent representations were that an operation of the type here involved was not serious and was practically certain to effect a cure. Obviously, the plaintiff was not obliged to wait for the outcome of her own operation in order to discover whether or not the representations were true. Even before the operation was performed at all, she by inquiry from the medical profession could have ascertained whether the operation was of the nature represented by the defendant, whether it was serious or inconsequential, and whether it was speculative or almost certain in its results. While the running of the statute is postponed where by some independent act of fraud or concealment a wrongdoer prevents discovery, there was no evidence of any such independent act on the part of the physician.

The judgment in favor of the physician was accordingly affirmed—*Bernath v Le Fever (Pa)*, 189 A 342

Health Insurance Disease Defined—The defendant insurance company agreed to pay the plaintiff certain benefits if he became "totally and permanently disabled, as a result of bodily injury or disease occurring and originating after the issuance" of two policies of insurance, issued in 1927 and 1928, respectively, thereby preventing him from engaging in any occupation and performing any work for compensation or profit. In July 1929 the insured was forced to cease work because of hypertrophic arthritis. For five years the insurance company paid the benefits. It then ceased payments, contending that the plaintiff's disability arose out of a disease originating before the issuance of the policies. The plaintiff brought suit on the policies and obtained a judgment in the trial court. The insurance company brought exceptions to the Supreme Judicial Court of Massachusetts.

There was no expert testimony, said the court, that the disease causing the plaintiff's disability first appeared after the policies were issued. Six physicians were called as witnesses, four testified that the plaintiff must have suffered from the disease before the dates of the policies and the other two expressed no opinion on the question. The testimony of the plaintiff alone, to the effect that he had no trouble until July 1929, tended to show that the hypertrophic arthritis appeared after the year 1928. The trial court ruled that "The word 'disease' means an active or efficient deviation from the healthy or normal condition of any of the functions or tissues of the body, an abnormal alteration of the state of the body or of some of its organs which interrupt or disturb the performance of the vital functions, and result in pain or weakness." This ruling was erroneous, said the Supreme Judicial Court. A disease may exist without pain or weakness. Even if it be assumed that the insured was afflicted by progressive hypertrophic arthritis before 1927, under this ruling the plaintiff could not be found to have had a "disease" before July 1929 if he felt no ill effects until that time. This result is not in accord with the layman's idea of disease, which is satisfied if the abnormal alteration causes or threatens pain or weakness. In *Mejer v Fidelity & Casualty Co of New York*, 96 Iowa 378 65 N W 328, 59 Am St Rep 374, the court said

By the use of the word disease we desire to convey the impression of a morbid condition resulting from some functional disturbance or failure of physical function which tends to undermine the constitution. We do not as a general rule apply [the] term to a slight and temporary disorder or to the imperfect working of some function which is over in a short period of time and which when recovered from leaves the body in its normal condition. In using [the word] we do not as a rule refer to a slight and mere temporary disturbance or enfeeblement. If this is true of our ordinary speaking and writing it is certainly clear that the [word] should be given no broader meaning when we find [it] used by an insurance company in a clause of its policy which it relies upon to defeat a recovery thereon.

The Supreme Judicial Court thought it plain that a man who, although he appears to be in sound health, suffers pain or weakness or who suddenly dies as a direct result of some abnormal condition of his body, without suffering in any way, has in the common speech of persons, a "disease." The ruling made by the trial court impliedly denies this possibility.

The Supreme Judicial Court accordingly sustained the exceptions brought by the defendant company—*Palumbo v Melro politan Life Ins Co (Mass)*, 5 N E (2d) 836

Workmen's Compensation Acts Strangulation of Pre-existing Hernia Compensable—The worker, while engaged in the course of his employment in lifting railroad ties, sustained a strain which resulted in the strangulation of the contents of an existing hernial sac. A gangrenous condition ensued and an operation performed three days later failed to avert death. An award of compensation in favor of the widow by the workmen's compensation bureau of New Jersey was affirmed by the court of common pleas but was reversed by the supreme court. The widow then appealed to the Court of Errors and Appeals of New Jersey.

The workmen's compensation act specifies, in detail, the circumstances under which a hernia must occur in order to constitute it a compensable injury. The intermediate appellate court, the supreme court, held that the death was not compensable because the hernia did not occur under the circumstances set forth in the act. But, said the Court of Errors and Appeals, the reasoning of the supreme court did not take into consideration the essential difference between the occurrence of a hernia and the traumatic aggravation of that bodily infirmity. Manifestly, the workman in this case could not have met the requirements of the act, for the hernia did not follow but long preceded the accident made the basis of the claim for compensation. His widow did not seek compensation for the hernia but for the death directly traceable to the accidental aggravation of the pre-existing disease condition of body. Concededly, the workman's death was caused by the strangulation and the supervening gangrenous condition of the intestinal content of the hernial sac. If extraordinary strain resulting from the lifting of the ties was the causative agent of the strangulation, the fatality was the consequence of an accidental injury within the meaning of the New Jersey workmen's compensation act. The workmen's compensation bureau found there was a definite and direct relation between the accidental strain suffered by the workman and his death three days thereafter. An accident which sets in motion the undeveloped and dangerous physical conditions with mortal consequences, is properly classable as the proximate cause of the fatality. The court, therefore, reversed the judgment of the supreme court and ordered an award for the widow—*Furferi v Pennsylvania R Co (N J)*, 189 A 126

THE AMERICAN RHEUMATISM ASSOCIATION

*Fourth Annual Meeting and Sixth Conference on Rheumatic Diseases
held in Atlantic City N J June 7 1937*

LORING T SWAIN, M.D., Boston Secretary

The Diagnosis and Cure of Rheumatoid Arthritis

DR RUSSELL L CECIL, New York Perhaps the most important problem which confronts a young medical organization such as the American Rheumatism Association is the proper orientation of the society in the field which it proposes to cover. The next task is to attack the problems of nomenclature. This has already been done in England. For example, the British National Committee divides rheumatoid arthritis into two main divisions: (1) rheumatoid arthritis with associated factors, (2) rheumatoid arthritis with no known associated factors. It seems to me that this division of the disease into two groups is hardly justified. The two types present the same pathologic and clinical manifestations and the immune responses are the same for the two groups.

In discussing the necessary criteria for the diagnosis of rheumatoid arthritis, one may divide them into pathologic, clinical, radiologic and serologic observations. The pathologic observations are quite definite but unfortunately are not obtainable except by means of biopsy. The clinical criteria are the most important of all, and of these the most characteristic are the fusiform finger and the multiplicity of joints involved. Subcutaneous nodules are also a valuable sign when present. The x-ray appearance of the bones and joints in rheumatoid arthritis is highly characteristic, so much so that it is usually possible to make a diagnosis of the disease by this means alone. The most characteristic blood change in the rheumatoid arthritis is the agglutination of *Streptococcus haemolyticus* by the patient's serum, usually in high dilutions. This test is positive in a large percentage of cases, the actual percentage of the positive reactions depending on the duration of the disease. Another reaction of considerable importance is the sedimentation rate of the red blood cells. A moderate grade of leukocytosis with some increase in the percentage of immature cells is seen in many cases.

What are the criteria for determining the cure of rheumatoid arthritis? Many writers fail to take into account the natural tendency of the disease to remissions and exacerbations. I believe that the first requirement for cure would be freedom from pain and swelling of the joints and a partial or complete return of joint function. The patient should also feel well and should be entirely free from the exhaustion and fatigue that so frequently accompany the disease. In the cured case the sedimentation rate should return to normal and the specific agglutinins with the hemolytic *streptococcus* should disappear.

It would be worth while for our society to appoint a committee whose duty it would be to set up certain criteria for the diagnosis and cure of rheumatoid arthritis. Copies of these criteria should be in the hands of every member of the society.

DISCUSSION

DR DOUGLAS TAYLOR, Montreal, Canada A table published in the June issue of the *Canadian Medical Association Journal* uses x-ray changes for grouping. In stage 1, while a decalcification is present there is no joint change. In stage 2 there is a definite retraction of the joint space with loss of cartilage or bone and further increase of decalcification and osteophytes or spurs. In the third stage there is a definite deformity with subluxation, and in the fourth stage there is destruction of the joint and ankylosis. The clinical features fit in well with these four roentgenologic stages. In the first stage there is slight

pain and stiffness, in the second, moderate pain, stiffness and crepitus, with prolonged limitation of motion in the various joints. In the third stage the patient has severe symptoms, with deformities and limitation of motions. These patients may be able to walk but require assistance, they are definitely incapacitated and not able to work. In the fourth stage the patient is usually bedridden and confined to home or institution. We have used this method in our clinic at the Royal Victoria Hospital, Montreal, for the last year and a half. I am submitting it as a means to help group arthritic patients. It is devised for rheumatoid and osteoarthritis but with slight modification can be used for any type of arthritis. There are certain cases difficult to classify correctly, but in the main I think these divisions should prove useful. The chart is published in the June issue of the *Canadian Medical Association Journal*.

DR RUSSELL L CECIL, New York I think that Dr Taylor has a fine idea. This is one of the phases of arthritis that the Committee on Nomenclature should take up.

Environmental Factors in Rheumatoid Arthritis

DR STANLEY COBB, ISABEL WHITING, M.A., M.S., and DR WALTER BAUER, Boston Fifty patients with rheumatoid arthritis were interviewed in the arthritic outpatient department clinic or in the wards of the Massachusetts General Hospital. The cases were not selected. The social worker, during about an hour's interview, recorded on a life chart the social data. Later the social worker or one of the physicians filled in the history of the arthritis. Any chronological correlation between attacks of arthritis and environmental stress then became apparent and was indicated in black in the middle column of the life chart. In the ordinary case record the important points are often entirely missed, e.g., that Mary's symptoms began a week after her engagement was broken or that John's began the year he lost his good job and had to begin on new and uncongenial work.

Summarizing the facts in the fifty life charts, in thirty-three cases out of fifty there seemed to be a significant relationship, in seven such relationship was doubtful, and in ten it was entirely lacking. The commonest environmental burden chronologically associated with arthritic attacks was unhappiness within the family (eleven cases); three of these situations led to separation of husband and wife. Severe financial worry coincided with attacks in ten cases. The loss of a parent or spouse preceded the attack in seven cases. Other forms of stress or combination of these were associated with onset of symptoms in the other five cases. The situations were usually complex and therefore simple classifications are unsatisfactory, but the main facts seem to be significant, although the interviews were too short to obtain reliable psychologic data. Nevertheless this survey indicates a relationship between emotional stress and the attacks of rheumatoid arthritis in 66 per cent of fifty cases.

Ten of the fifty cases showed no relationship. In seven the data were equivocal, no definite coincidence in time between the appearance of symptoms and the history of environmental stress could be made out, although the same factors of worry, uncertainty and unhappiness appeared in the life histories of these questionable cases as in the thirty-three in which the relation was obviously significant.

In this limited survey a relationship between environmental stress and onset (or exacerbation) of arthritis is brought out by the life chart in two thirds (66 per cent) of the fifty cases. For a further demonstration of this relationship an intensive study of a few patients is needed. This is being done by Dr Giles Thomas in New York. It is also important to have more control material. So far, we have examined twenty-five cases of varicose ulcer in exactly the same way as with rheumatoid arthritis. Varicose ulcer was chosen because it is a disease with rather obvious etiology and attacks people in about the same age and sex group as the arthritis. In twenty-five cases examined in this way there were only two in which there appeared to be a coincidence in time relation between the onset of the ulcer and social stress in the environment. There were no cases that seemed of doubtful significance and twenty-three showed no significant relationship.

DISCUSSION

DR. GILES THOMAS, New York A year ago I reported a series of thirty-one cases and the observations were in general agreement with those of Dr Cobb and his co-workers. I found what I thought was a significant emotional factor in all cases. I think I went into somewhat more detail in the psychiatric examination, and also my series was smaller than theirs. This may account for the discrepancy, but perhaps it is not important. If one can find an important emotional disturbance in every case of rheumatoid arthritis, what significance has the observation? As soon as one begins to discuss this problem, one is told that significant emotional disturbances can be found in any one, and, the informant adds, "if you examine the department of medicine you will find just as much, and if you examine the department of psychiatry, twice as much." In spite of these difficulties, I think it is possible to come to some conclusions. The authors' series of controls of patients with varicose ulcer indicates this. There is another controlled series now being studied by Dr Ludwig in Dr Bauer's clinic. *Gonorrheal arthritis often resembles rheumatoid arthritis, but uncomplicated gonorrhea occurs also.* It occurred to Dr Ludwig that if uncomplicated cases of gonorrhea and cases of gonorrheal arthritis were both examined psychiatrically, the cases of uncomplicated gonorrhea might serve as controls. *The infection would be the same in the two series, and if the incidence of emotional disturbance differed greatly in the two series it might be possible to draw some conclusions about the role of emotional factors in gonorrheal arthritis, and perhaps by analogy in rheumatoid arthritis.* I have not examined any cases of uncomplicated gonorrhea psychiatrically, but I have seen a few cases of gonorrheal arthritis and have found that the same psychic disturbances are present as in rheumatoid arthritis. If it is assumed that emotional disturbances play a part in the genesis of rheumatoid arthritis, through what mechanism could this influence act? Emotional disturbances have a definite and pronounced effect on physiologic function, and it seems reasonable that a prolonged disturbance of physiologic function could give rise to structural changes, with or without the presence of infectious or traumatic agents. I find no difficulty in demonstrating emotional disturbances in patients with rheumatoid arthritis, but if this is a factor why should the patient get rheumatism rather than gastric ulcer, hyperthyroidism or some other disorder? This is a problem for which no answer is available. Perhaps there is a constitutional factor. An attempt to answer this question has been made by Dr G. C. Booth of New York. He compared patients with arthritis and paralysis agitans, and found significant differences in their modes of reaction which he believed were important in determining which diseases appeared. I feel that as yet there has not been enough work done to form a basis for drawing any conclusions. I think that the localization of the disease, that is, the joints involved, may often be influenced by psychologic factors in the same way that the localization of symptoms is determined in conversion hysteria. If the neurotic factor is as important in rheumatoid arthritis as I think it is, treatment of the neurosis should improve the arthritis. I have noticed that some patients I examined and talked with a few times seemed relieved after a discussion of their problems, and the arthritis was symptomatically better. A few were definitely upset and the arthritis worse. At the present I am psychoanalyzing two patients, but it will be some time before I shall be ready to make a report.

DR. H. ARCHIBALD NISSEN, Boston The work that Dr Cobb and his co-workers have presented is enlightening. If they can follow up each patient along the same lines, it will be interesting to hear their observations at the end of a five year period. I find that the patient's adjustment to his emotional problems, rather than the emotional problems per se, is the point of greatest importance. Such a study does not mean just one visit, it means repeated visits at the hospital, home or office. In time the patient usually volunteers information on changes in muscles and joints which his own observations have told him resulted from various emotional upsets. Thirty per cent of the group in which I have been particularly interested have become bedridden or wheel chair patients. Watching this group year by year, one finds as a characteristic

a contented emotionalism, so to speak—a rather smug self complacency. No matter what is done for that individual something else is always needed. For instance, one man started in with nothing more than a bruise on one knee, received when he slipped from the second step of a stepladder. It was a year and a half before he had hospital care. Had he been seen at this time and studied from a psychogenic point of view, the personality abnormalities might have been recognized before actual joint damage had occurred. They might have been corrected, or at least brought into the man's consciousness, thinking. Of course, they may have been too deep seated even at this time to be susceptible to change by recognition, but I believe that this type of joint reaction is evidence of severe psychosis. As it was, he had several operations: tonsillectomy, transfusions, teeth extractions, manipulations. At the end of a year he left the hospital worse than when he was admitted. Under new therapy he appeared to improve for a year, then the downhill course was resumed, as if the "will to be ill" had conquered the "will to be well." What can we do from a therapeutic point of view? First, by studying each patient's manner of adjustment we can estimate partially the degree of psychogenic maladjustment and the possible type of organic reaction (always bearing in mind Jelliffe's question "What price healing?"). Sometimes the somatic manifestations are less deadly than the psychic. Second, we can assist the individual to recognize such conditions and help himself, third, we may reach a correct prognosis more rapidly than when the body alone is studied and the patient's psychology is ignored. Coincidentally, the body and its physiology must be treated symptomatically and specifically. Dr Cobb has opened the way. If each year he will give the results of follow-up studies I know we shall learn a great deal more about the real importance of psychogenic factors as related to the origin, remission and relapse of rheumatic diseases.

DR. ROBERT B. OSGOOD, Boston An active medical man, about twelve years ago, with some worries began to have a typical rheumatoid arthritis, with some erosion of the bones. Rest and freedom from worry led to recovery except for one wrist by the very criteria Dr Cecil has mentioned. He carried on a heavy hospital service for eleven years without any return of his arthritis, but then a combination of worries that would have floored almost any man led to an exacerbation of his arthritic condition. The only thing that anybody has been able to find in his case is this accumulation of worry to account for the recurrence of his syndrome of rheumatoid arthritis. The worries were overcome, rest and therapeutic measures were instituted, and the patient is now prepared to go back to work. This is a striking case, helping to emphasize the point to which the authors have called our attention so well.

DR. ABRAHAM S. GORDON, Brooklyn I wonder whether the authors know of any one who has made a comparative study of a subject such as asthma. I mention this in particular because I believe that if such a study were made it would show as high a percentage as the one shown here in arthritis. Therefore, it brings us back to the original question of predisposition of the patient with the clinical syndrome of arthritis rather than merely the manifestations of arthritic symptoms.

DR. WALTER BAUER, Boston Rheumatoid arthritis is a disease of unknown etiology characterized by remissions and relapses. All are interested in knowing not only the cause of this disease but also the various factors responsible for the many unexplained remissions and relapses. In following a group of these patients from month to month, one sees many unexplained relapses. A careful history fails to elicit any one of the frequently mentioned precipitating factors, such as upper respiratory infections, constipation or physical trauma. In the same group, however, one can frequently elicit a history of the existence of disturbing environmental factors. Such disturbing factors in certain instances were present preceding the onset of the disease. I might briefly mention the history of a young woman whose marriage was postponed because her father fell ill with a severe arthritis. On the day planned for her marriage she noted for the first time swelling, redness and pain of the midphalangeal joint of the ring finger. Her arthritis gradually progressed so that now she is suffering from a fairly extensive rheumatoid arthritis. It is interesting

that the first joint involved was the midpharyngeal joint of the ring finger of the left hand. How do these emotional factors affect the individual? Undoubtedly some of the vasomotor and neurologic symptoms these patients complain of are a direct result of such environmental factors. However, one would like to know what other physiologic processes are affected. Do they result in actual disturbances of the physiologic function of the normal joint and thus play a major etiologic role? A better understanding of the anatomy and physiology of the normal joints is essential to a knowledge of how these factors operate. The answer to these and many other questions must be found before the role can be fully evaluated of such factors in the production of rheumatoid arthritis and the many unexplained remissions and relapses encountered. I doubt whether the emotional disturbances alone are ever the sole cause of the disease. I believe an infectious agent is necessary for the production of this disease state. Is it possible that either factor alone is incapable of producing the disease but the combination of the two results in rheumatoid arthritis? We do not know. Similar control studies will be carried out on a series of patients with gonorrheal arthritis. Dr Cobb is also making such a study in a group of asthmatic patients.

(To be continued)

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1927 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Treatment of Cervicovaginitis with Silver Picrate Suppositories—Kobak and Frankenthal find that silver picrate suppositories are easily used and find their way into all the crypts of the vaginal canal and still are not expelled prematurely with subsequent loss in efficiency. They have been used in the treatment of twenty-two cases of cervicovaginitis in children. The cooperation of the class of mothers that the authors were dealing with could be assured only when their duties were easy to comprehend and did not entail much effort. The suppositories were inserted nightly after the vulva between the labial folds was cleansed with bland soap. The suppository used was of such size that it should readily pass the hymen and of such length that it occupied the entire length of the vagina. It has a boroglycerin gelatin base. The dosage of silver picrate was 0.065 Gm to each suppository. It melted readily at body temperature and appeared to diffuse easily throughout the surface of the vagina into its crypts. The material was observed to adhere well to the vaginal surface with which it came in contact. The patients showed rapid and definite improvement, as evidenced by the quick disappearance of the discharge. The recorded observations of the mothers also confirmed this improvement. Five of the patients had a permanent negative smear after one week of treatment, and three became negative in three weeks. Four patients became permanently negative after six to nine visits to the clinic. Only one patient remained resistant to treatment and did not become permanently negative until fifteen visits had been made. The nonspecific group likewise showed a rapid response to this therapy.

Pathologic Processes of Small Intestine—Elward believes that the x-rays play a most important part in the early and accurate diagnosis of gastro-intestinal pathology. This is particularly true in the diagnoses of lesions of the duodenum, jejunum and ileum. The roentgen examination of the small intestine is a combined use of roentgenoscopy and roentgenography, a contrast medium, usually purified barium sulfate,

being used. If sufficient information is obtained to warrant a diagnosis of obstruction by roentgenoscopic and flat-film studies, a contrast medium should not be used, because the hard, inspissated masses of barium sulfate may interfere greatly with the surgical procedure necessary to afford relief. The roentgenoscopic method depends on the fact that the small intestine normally does not contain gas or fluid in sufficient quantities to form a level of fluid visible when the patient is examined in the upright position. It also gives some idea of the size of the small intestine and the location and duration of the obstruction. The method of using a contrast medium is particularly applicable to cases of partial obstruction in which the time element is not paramount. The method is of value in tuberculosis, hernias, anomalies, partially obstructive new growths, diverticula, displacements, ulcers and adhesions. Retention of twenty-four hours in the ileum may be considered pathologic if there are no factors, such as higher obstructive lesions, pyloric stenosis, gastric ulcer or duodenal ulcer, to interfere, or lower obstructive lesions, such as cancer of the cecum. An incompetent ileocecal valve may also account for the twenty-four hour ileac retention, this, however, is a regurgitation rather than a retention. The opposite condition is seen when the entire barium sulfate meal has passed into the colon in six hours, when hypermotility is said to exist. Repeated and detailed examinations should be made to determine the cause or causes, some of which are tuberculosis, simple ulcer, achylia gastrica and scirrhus carcinoma. A too large gastro-enterostomy stoma or purgative drugs may cause a pseudohypermotility.

Transmission of Poliomyelitis to Animals—Kolmer and his co workers attempted to transmit the virus of poliomyelitis of a single monkey passage strain to young rabbits, mice, guinea-pigs, chickens and ferrets with and without depression of the marrow and lymphoid tissues by x-rays. The inoculations were intracerebral, intravenous, intranasal, intraperitoneal and intracasternal. All animals were kept under daily observation for at least two months for any recognizable clinical evidences of infection, and the spinal cords of all those dying were examined microscopically for any histologic evidences of poliomyelitis. Of twenty young rabbits varying in age from 4 to 6 weeks variously inoculated, only one succumbed in twenty-four hours after intracerebral inoculation and all four after intravenous injection. None showed any recognizable clinical evidences of infection, and no lesions suggestive of infection of the spinal cord were found on microscopic examination. It may be, however, that infection occurred after intravenous inoculation, since all inoculated by this route died. In six ferrets inoculated intracerebrally and intraperitoneally, no clinical evidences of infection developed and none died. Twelve young guinea pigs were inoculated intracerebrally, intravenously and intraperitoneally. Three died with no recognizable lesions in the spinal cords and the surviving nine animals showed no demonstrable clinical evidences of infection. Sixteen white mice were inoculated intracerebrally or intraperitoneally, two of the ten inoculated intracerebrally died one and twelve days later but showed no lesions in the spinal cord. Three of the six inoculated repeatedly intraperitoneally also died with no demonstrable lesions of the spinal cord. Sixteen chickens of mixed breeds and both sexes were inoculated intracerebrally, paresis of one or both wings with emaciation and general muscular weakness developed in four and death ensued in from seven to fourteen days later. Four animals inoculated intracerebrally with virus after mixture with convalescent immune serum containing antiviral antibody remained perfectly well. Under the circumstances and in view of the symptoms presented by four chickens that died the authors were hopeful of the successful transmission of the virus, but in consultation with Dr Stubbs it was suggested that the illness of these chickens was due to avitaminoses. A repetition of the experiment during which the chickens were kept on a better diet gave completely negative results and in the meantime a careful microscopic examination of the spinal cords of the four chickens revealed no histologic evidences of poliomyelitis. Certain of the s dis

in mice are being continued to determine the possibility of infection of other tissues and especially of the organs of the reticulo-endothelial system

Typhoid Carriers—McBurney states that weekly examinations of the stools of seven typhoid carriers covering fifty-two weeks showed that the number of positive stools among women was 15 per cent higher than among men. There was no correlation among adults referable to age, duration of the carrier state and the percentage of positive stools. The well established positive group was positive 87 per cent of the time. There was practically no negative phase among them. Temperature, humidity, diet, mode of living, minor illness and other factors studied did not alter the carrier state. Increasing temperatures and humidity during the warmer months did not produce a positive phase among the four carriers who had consistently negative stools. For the seven positive carriers there were never more than two negative stools in any one week and not one positive carrier had a negative stool more than two successive times. Of twenty-four weekly fecal specimens from seven well established typhoid carriers, typhoid bacilli averaged 49.45 per cent of the bacterial flora. Considering the results obtained from the whole group studied throughout the year, coupled with the hot room experiments, it seems justifiable to conclude that changes in temperature, humidity, environmental and other factors studied had no effect on periodicity.

Toxicity of Fluorine Compounds—Kempf and his associates found that the oral administration of from 0.45 to 4.52 mg of fluorine as sodium fluoride per kilogram of body weight caused no effect on total calcium, acid-soluble inorganic phosphorus, hemoglobin or coagulation time of the blood of the dog. Roentgenograms indicate that there are no changes in the bones of dogs which received 4.52 mg of fluorine as sodium fluoride orally per kilogram of body weight. Alpha fluoronaphthalene produced mottled enamel whereas the ingestion of p , p' difluorodiphenyl, p fluorobenzoic acid and fluorobenzene had no effect on the teeth. Fluorine in water has been lowered by treatment to from 1.5 to 2 parts per million from an original concentration of 8 parts per million. Acidity of the water is a factor in the removal of the fluorine by aluminum sulfate. This is in part due to the nature of the floc produced under different hydrogen ion concentrations. Calcium silicofluoride and cupric fluoride caused mottled enamel, whereas ingestion of aluminum fluoride did not produce this effect. The ingestion of aluminum sulfate, simultaneously with fluorides, prevents, or at least markedly reduces, the effect of fluorine on the teeth.

Dextrose Tolerance in the Aged—Deren studied the dextrose tolerance of fifty subjects more than 55 years of age (free from acute infections, diabetes mellitus and glomerular [hemorrhagic] nephritis) admitted to the hospital for a variety of conditions, particularly, heart disease, osteoarthritis, hypertension and arteriosclerosis. The fifty subjects were divided into equal groups. One group was investigated by the standard method (100 Gm of dextrose after an overnight fast) and the other group by the Eaton-Rose procedure (two 50 Gm doses of dextrose given at an interval of thirty minutes after an overnight fast, abstracted in *THE JOURNAL* Nov 3, 1934, p 1405). The blood sugar was determined by the method of Folin and Wu and the urine sugar by Benedict's method. The results with the standard test indicate that in the aged the fasting blood sugar is normal, the highest being 113.4 mg per hundred cubic centimeters. The peak of the curve is generally delayed, varying from one to two hours. The duration of the curve is prolonged, in most instances exceeding two hours. Sixteen cases with high prolonged, five with prolonged and four with normal blood sugar curves were observed. Urine volumes were small, and in many instances none could be voided throughout the length of the test. In the one hour two-dose dextrose tolerance test the fasting blood sugar levels are comparable to those of the first group. An analysis of these data according to the criteria postulated by Eaton and Rose revealed twenty-one diabetic and four normal types of sugar curves.

*Treatment of Menopause Syndrome by Irradiation of Pituitary Gland R Zollinger and W W Vaughan, Boston—p 219

Treatment of Menopause by Irradiation of Pituitary—Zollinger and Vaughan employed irradiation of the pituitary body in the treatment of fourteen women who complained of varying degrees of discomfort during the menopause. The majority were having severe symptoms. At least one half of these patients had taken various kinds of ovarian preparations and sedatives with little or no benefit. Most of the patients selected for treatment complained of insomnia because of the hot flashes, accompanied by marked perspiration. The menopause followed surgical castration in seven patients, roentgen therapy in four and application of radium in one and was of natural occurrence in the remaining two cases. The duration of symptoms, before radiation therapy was instituted, varied from two months to eight and one-half years. Of the fourteen

patients treated at least nine months to one year ago, five had a definite and sustained decrease in the number of hot flashes and marked symptomatic improvement, three other patients stated that they were definitely improved, although by tabulation there was little if any change in the number of hot flashes. The remaining patients were not improved subjectively, and the number of hot flashes remained at a preirradiation level. The patients showing definite improvement recorded a fall in the number of hot flashes about the third day of therapy. Although a standard of from 1,400 to 1,600 roentgens was given over a period of four days, this quick response may be taken as an indication that benefit could be expected from smaller doses, such as 800 roentgens. To rule out the psychic effect of x-ray treatment three patients were given sham therapy, two reported a decrease in the intensity of the flashes. Three of the five patients who were definitely improved had had castration by surgery within a year of the onset of treatment. The average age of the improved patients was 36, which is six years below the average for the entire group. Basal metabolic and sugar tolerance determinations were made before and at intervals after the irradiation in order to check any possible damage to the diabetogenic and thyrotropic hormones, but there was no remarkable deviation from the preirradiation studies. In two of the cases there was a slight flattening of the sugar-time curve, which was not extreme enough to be more than coincidental. Biopsies of the vaginal mucosa were obtained in ten patients before and a few weeks after irradiation. The specimens obtained prior to irradiation corresponded in all respects to postmenopausal vaginal mucosa. No definite change after irradiation could be found, even in patients showing marked clinical improvement.

 *Peripheral Vascular Disease—Simple External Suction J. Tenopir and B. G. P. Shafiroff Brooklyn—p 1387

Peripheral Vascular Disease—Tenopir and Shafiroff constructed a simple suction device for the treatment of peripheral vascular disease. The apparatus can be easily assembled in any hospital and can be more generally used by the profession with the knowledge that the same physiologic benefits can be obtained as with a commercial pattern. It consists of the regular portable suction machine used for surgical aspiration connected to an airtight chamber or boot by rubber tubing. Before the extremity is inserted into the boot, a properly fitting nonconstricting rubber tube encircles the leg or thigh. These tubes resemble in appearance the inner tube of an automobile tire and are of various sizes. The extremity encircled by its inflated tube seals the proximal end. The outlet on the boot is connected to the suction machine by pressure tubing. The button on the suction base permits the patient to start and stop the negative pressure when the treatment period is ended or the sensation of pain is present. Treatments are given at minus 30 to minus 50 mm. of mercury maintained continuously for from one-half to two hours, according to the patient's tolerance. It is possible to use suction at a continuous constant negative pressure by inserting small objects between the tube around the leg and the outside to permit a small air leakage. The clinical results are a confirmation of the beneficial effects reported by other workers with the passive vascular exercise machine. Relief from pain was noted in twelve of the sixteen cases treated by this method. Three of Buerger's disease, twelve of diabetic arteriosclerosis and one of severe frostbite of the lower extremities. Capillary ecchymosis directly due to suction developed in one case. Two cases of gangrenous toes, in which amputation was considered, healed completely. Six arteriosclerotic patients reported relief from pain and improvement in

walking distance. The case of frostbite responded well to suction by improvement in skin texture and relief from persistent coldness of the feet, cessation of pain while walking was also experienced. No other treatment was used in any of these cases during the course of suction therapy.

Surgical Aspects of Epilepsy—Gilbert points out that by far the greatest benefits that epileptic patients derive from surgery are those offered by neurosurgery in the removal of tumors. Many feel that, in the epilepsy due to trauma, surgery has distinct benefits that it can offer. Foerster and Penfield have shown that, in many instances wherein injury has occurred, extensive cerebral scars exist. The injury-induced epileptic attack begins after a rather long period of time has elapsed from the date of injury, suggesting that the slow contraction of the scar was responsible. The treatment suggested is the removal of the overlying scar tissue, the identification by faradic current of the part of the cortex governing movements in the extremity wherein the attack arises and the radical excision of that portion of the cerebral cortex. Favorable results are reported by these and others doing this operation. Contrary to popular opinion, permanent paralysis does not follow this operation—the temporary paralysis in most instances gives way to almost complete return to normal. The treatment of Jacksonian epilepsy due to trauma or atrophy by means of alcoholic injection into or electrical coagulation of the trigger-zone portion of the cortex has been reported with favorable results by Fincher and Dowman. Several cases of

pancreatic adenoma have been reported in which the hypoglycemia produced by such a growth was followed by epileptic attacks. Surgical removal of such adenomas was followed by alleviation of these attacks. So-called essential epilepsy and surgical measures suggested for its control are considered. These include in operation which mobilizes the transverse sinus where the anomalous development has been identified, bilateral adrenal denervation and injection of air. Three cases with epilepsy as part of their complaint are reported in which injection of air was beneficial.

Sulfanilamide in Treatment of Erysipelas—Snodgrass and Anderson treated 312 cases of erysipelas under controlled conditions with ultraviolet radiation sulfanilamide ultraviolet radiation and sulfanilamide or scarlet fever antitoxin. There was an even distribution of the individual cases in the treatment groups in respect of factors known to influence the course of the disease, the duration of the disease before admission to the hospital, the age of the patient, the severity of the infection and associated diseases. The average case dosage of sulfanilamide was 5 Gm and the average duration of treatment was two days. Treatment was given during the acute stage only and was not maintained after the subsidence of the local lesion and the cessation of fever and toxemia. Cases in which sulfanilamide was employed showed better results in respect to the duration of the spread of the local lesion, the duration of primary pyrexia and the duration of toxemia. The benefits due to sulfanilamide in erysipelas are statistically assessable and are great enough to render its use advisable until some better form of treatment is available. The action cannot on the whole be termed dramatic.

Agranulocytosis and Sulfanilamide—A consideration of the formula of sulfanilamide suggested to Young the possibility that this drug might be capable of producing agranulocytosis. It was decided to make observations on the leukocytes in sulfanilamide-treated patients. Complete agranulocytosis with fatal result occurred in the second case investigated. While the possibilities are obvious, it naturally cannot be determined whether this occurrence was or was not due only to the administration of the drug. The patient was a man of 53 suffering from acute rheumatism with pains of the joints and pyrexia. There was a history of previous attacks in 1901, 1908 and 1914. The condition failed to respond to salicylates, and sulfanilamide (3 Gm daily for eighteen days) was given. At the end of this period the clinical condition had deteriorated, the temperature running at a higher level than before and treat-

ment was stopped. Four days afterward complete agranulocytosis was found, and culture of the blood, which had given no growth three weeks previously, now gave hemolytic Staphylococcus aureus and Streptococcus viridans. The patient died on the following day. Cases of agranulocytosis have been recorded in which no drugs appear to have been taken and no obvious cause could be found, so that a definite conclusion with regard to the causation in the present case is not justified. The only drug of the benzene ring administered within twenty-four days of the development of agranulocytosis was sulfanilamide. The agranulocytosis appeared to be either of the idiopathic type of unknown etiology or to be due to sulfanilamide.

*Extreme Degree of Leukocytosis in Whooping Cough W J Pearson and G H News — p 254

Extreme Leukocytosis in Whooping Cough—Pearson and News cite a case of whooping cough with a high leukocyte count (145,000 per cubic millimeter) and a relative increase in the lymphocytes. This feature of the blood picture is therefore much more valuable diagnostically than either the propor-

tion of lymphocytes or the level of the leukocyte count. Unlike those in lymphatic leukemia, these were mature in form. Such high counts are extremely rare and seem to be associated with a complicating bronchopneumonia. In the present case there is little evidence that it has influenced the blood picture.

Journal de Medecine de Bordeaux et du Sud-Ouest

Erythrodermia Desquamativa Boissier Lacroix—p 121

*Meningeal Hemorrhage of the New Born M Riviere—p 129

Subarachnoid Meningeal Hemorrhages of Children (Except the New Born) M Traissac—p 145

Meningeal Hemorrhages of the New-Born—Riviere discusses the meningeal and ventricular hemorrhages which, because of their anatomic importance, may give rise to clinical symptoms. He disregards the microscopic meningeal hemorrhages, which according to Tassovatz occur in ninety-five out of 100 normal deliveries. The incidence of meningeal hemorrhages that cause clinical symptoms has been estimated differently by various authors. Whereas Waitz judged them to be 11 per hundred, Tassovatz estimated them at 0.05 per hundred. In summarizing his observations the author says that their incidence may be fixed at about 1 in 100 cases. Their etiology is dominated on the one hand by syphilis and prematurity, often concurring, and on the other hand by obstetric traumatism. The etiologic responsibility is about equally divided between the predisposing factors (syphilis and prematurity) and the trauma. There are four chief mechanisms: (1) intracranial venous hypertension of circulatory origin, (2) sudden thrusts of the cerebrospinal fluid in the arachnoid spaces, (3) ruptured vessels in the cerebellar tentorium and (4) in exceptional cases direct vascular lesions by pieces of bone. The symptomatology differs according to circumstances. There may be real or apparent death or atypical symptoms of muscular hypertension with attacks and clonic convulsions. The cortical and bulbar centers may be inhibited or irritated by a subdural hematoma. The ventricular hemorrhages become manifest by stupor, the signs of cortical irritation do not appear until later. The clinical diagnosis can always be corroborated by lumbar, suboccipital or ventricular puncture. The immediate prognosis is grave in that the mortality exceeds 35 per cent. The late prognosis is indefinite if suitable treatment has not been employed, for a large number of encephalopathies derive from intrapartum meningeal hemorrhages. The prophylactic treatment should ameliorate the predisposing factors by combating syphilis and prematurity and should make efforts to reduce or suppress the obstetric traumatism by careful choice of the interventions. The curative treatment should decompress the centers by lumbar, suboccipital or ventricular punctures. They should be repeated as often as signs of intracranial hypertension exist. Hemostasis is produced by assuring the normal play of respiration and by injections of hemostatic serum or of maternal blood. This treatment, which relieves the cortex of the compressive and destructive action of the subdural hematoma, seems to improve greatly the late prognosis of the meningeal hemorrhages of the new-born.

*Tuberculous Tracheobronchial Adenopathy with Rapid Progress in Young Adults C Roubier—p 423
Frequency and Dangers of Unrecognized Foreign Body of Respiratory Tract P Mounier Kuhn—p 435

Tuberculous Tracheobronchial Adenopathy in Young Adults—Roubier says that all authors agree that tuberculous tracheobronchial adenopathy is a rarity in adults in France. Whereas in young children the involvement of the lymph nodes often predominates over the pulmonary lesion, in adults it is usually the adenopathy, which is insignificant compared to the pulmonary lesion. To be sure, there are exceptions to this general rule, for instance, in young adults one may observe, although rarely, adenopathies that consist of enormous caseous masses in the mediastinal lymph nodes and in those around the pulmonary hilus, much like those that are observed in young children. In this paper the author describes the clinical history of a young adult, aged 19 years, who had tuberculosis of the lymph nodes. The process, the total duration of which did not exceed eight months, evolved in three periods. During the

first period there existed an adenopathy of the lymph nodes of the left pulmonary hilus. This process was accompanied by continuous fever. During the second period the tuberculosis extended to other groups of lymph nodes. During the third the terminal, period the lung became involved. On the basis of serial roentgenologic examinations and of the necroptic observations, the author concludes that the primary tuberculous process was in the lymph nodes and that the lung became involved only secondarily. He points out that this is a case of primary tuberculous infection of an adult which is comparable in all points with those which during the World War were often observed in the representatives of the primitive races, particularly the Senegalese.

*Oral Administration of Ouabain in Treatment of Cardiac Insufficiency S Livieratos and N Kisthinos—p 1178
Surgical Organization of Hospitals and Operative Blocks. G Renon—p 1180

Oral Administration of Ouabain in Cardiac Insufficiency—Livieratos and Kisthinos point out that the administration of ouabain by the oral route was already recommended by Vaquez but that later it was abandoned in favor of the intravenous injection. After remarks about the intramuscular injection in which they mention the toxic effects on the muscle, they give their attention to the oral administration, citing the experimental studies of Dimitracoff and others, which proved that the oral administration of strong doses produces results that are comparable to those of intravenous injection and that this mode of administration should be resorted to whenever the intravenous administration is impossible, such as in the treatment of cardiac insufficiency. On the basis of these observations, the authors decided to try the oral administration of ouabain in advanced cases of cardiac insufficiency, to replace the formerly employed intravenous injection of the substance. In about twenty cases they used a 2 per cent solution of ouabain, giving from 20 to 25 drops twice a day, in the morning before breakfast and in the evening before retiring. The patients tolerated these doses well and the condition commenced to improve on the following day. Although stronger doses have been recommended by some authors and in the literature accompanying the preparation, the authors warn against larger doses, since they may provoke undesirable complications without being more efficacious against the cardiac insufficiency. The indications for the oral administration of ouabain are the same as those for the intravenous injection, except in the urgent cases, in which nothing can replace the intravenous injection. To be sure, the oral administration of ouabain is not an infallible method, for there are cases in which it fails. If, after two or three days of oral medication, the desired improvement has not been obtained, the intravenous method should be instituted without further delay.

*Death from Application of Salicylic Acid Salve Case G Sannicandro—p 273
Cutaneous Gangrene of Streptococcal Origin Experimental Study of Case L Peruccio—p 282
Nonvenereal Diseases of Genitalia Cases C Pisacane—p 286

Death from Application of Salicylic Acid Ointment—According to Sannicandro, the skin of children is extremely sensitive to the application of preparations containing salicylic acid. He reports the case of a child, aged 7 years, who entered the clinic in excellent health except for the fact that he was suffering from benign psoriasis at the trunk, knees and elbows. An ointment containing 5 per cent salicylic acid was applied to the psoriatic areas of the skin. The patient was placed in bed covered with impermeable sheets. Twelve hours later he showed a grave condition with intense vomiting, fever, nervous symptoms, hyperdyspnea, acidosis and coma. Tests showed that there was salicylic acid in the urine and cerebrospinal fluid. The amount of sugar in the blood was normal. All treatments failed. Death occurred forty hours after application of the ointment. At necropsy it was found that the skin, both psoriatic and normal, was the seat of a swelling process which explained the exaggerated passage of the acid to the body.

The brain and viscera, especially the liver and kidney, were the seat of vascular congestion and tumefaction. The author points out the danger of applying salicylic acid preparations to children. He also points out the fact that the therapeutic dose of salicylic acid in adults varies with the individual, according to the presence or absence of a congenital or acquired sensitivity.

- *Bactericidal Power of Gastric Juice Relation Between Acidity and Bactericidal Power of Gastric Juice A Sebastianelli—p 1593
Blood Transfusion in Clinical Medicine M Lusner—p 1602

Bactericidal Power of Gastric Juice—Sebastianelli studied the relation between gastric acidity and the bactericidal power of the gastric juice. His researches were carried out for three consecutive years on several thousand specimens of gastric juice in normal or in pathologic conditions. The juice was withdrawn in all cases from fasting stomachs immediately before and for two hours after administration of a broth meal. In all cases the gastric juice was neutralized if it was not neutral. The bactericidal power of the juice was determined by the action of the latter on a 1:250,000 solution of a twenty-four hour bouillon culture of colon bacilli *in vitro*. According to the author, there are two types of bactericidal power of the gastric juice. The first type is a property of the juice. It is independent of the antiseptic properties and production of the gastric hydrochloric secretion. It depends neither on the intensity of free and total acidity nor on the presence of a normal gastric secreting reaction to a standard stimulus. The second type of bactericidal power of the gastric juice is related to the intensity of gastric acidity. It is of less importance than the proper bactericidal power of the gastric juice. In the absence of the latter, an intense acidity of the juice is necessary for the maintenance of sterility. An intense acidity of the gastric juice in fasting stomachs is found only in exceptionally rare cases (31 per cent, according to the statements of the author). In these cases the relative bactericidal power causes the same effects on bacteria as those caused by the proper bactericidal power of the gastric juice.

*Arterial Hypertension Treatment by Diathermy of Carotid Sinus R Gorlero Pizarro and P Levisman—p 1625
Treatment of Heine Medin Disease V C Girardi—p 1628

Diathermy in Arterial Hypertension—Gorlero Pizarro and Levisman resorted to diathermy of the carotid sinus in the treatment of arterial hypertension. Patients who improved by rest were excluded. Diathermy was administered by means of an apparatus which consisted of two common electrodes 8 cm long and 2.5 cm wide (positive poles) and a common diathermy square plate of 12 cm (negative pole). The electrodes were placed at the carotid region, whereas the plate was placed at the pectoral region. The diathermic applications were given every other day to patients with a fasting stomach. The first application lasted ten minutes. The duration of the following applications was increased by five minutes for each application up to a duration of thirty minutes. The treatment consisted of six or seven sittings. The group was made up of forty patients. Thirty patients suffered from essential hypertension. The other ten had arterial hypertension from nephrosclerosis. The thirty patients suffering from essential hypertension were relieved from headache and dizziness and became euphoric. The blood pressure, maximal and minimal, was lowered 2, 3 or 4 cm in twenty patients of the group and hypertension did not change in ten patients. In the group of ten patients who were suffering from hypertension and nephrosclerosis the treatment modified neither the symptoms nor the blood pressure. The treatment is harmless. According to the authors, the factors that induce lowering of essential hypertension are sympathetic reflexes and dilatation of the arteries and veins induced by diathermy of the carotid sinus.

Arterial Oxygen Deficit and Pulmonary Collapse—Vorwerk says that in most instances the clinical and roentgenologic aspects determine the desirable degree of pulmonary collapse. However, it is difficult to recognize whether the extent of the pulmonary collapse impairs the adequate arterialization of the blood. Increase of the collapse beyond a certain point reduces the favorable therapeutic effect of pneumothorax and other collapse measures. In this connection the author calls attention to anoxic stimulation of the respiration and many other unfavorable effects of arterial oxygen deficits. Whether arterialization of the blood is complete or not can best be determined by spirometry. The author reports his observations with spirometry in 100 patients. He tested the arterial saturation by means of the closed gas exchange system of Knipping, in which the patients are changed from the breathing of air to the inspiration of oxygen so that they are not aware of it. Toward the end of the inhalation of oxygen, the vital capacity and the respiratory limits are determined. Spirometry was done chiefly in patients who readily developed dyspnea or in those in whom both sides of the lung were involved or in those in whom collapse therapy was done. Several patients were examined before and after an artificial pneumothorax was made. Some patients with bilateral pneumothorax were examined immediately after the filling. The author gives a tabular report of the results of the tests and discusses some of the characteristic cases. He shows that even in normal subjects there may be slight arterial deficits during rest. However, because it is so slight, this normal deficit may be disregarded in the tests. In one of the cases which the author discusses in detail it is shown that the filling of the pneumothorax was not excessive but that the patient required rest, for even slight exertion resulted in incomplete arterialization. He also found that phrenic exeresis is unfavorable from the point of view of respiratory function and arterialization. Whereas the diseased lung is only slightly collapsed, the immobilization is doubtless more complete than is the case in pneumothorax. The blood perfusion of the immobilized side is not greatly restricted. If the other side of the lung is entirely normal, the arterialization is hardly impaired. However, if the other side of the lung becomes involved in the tuberculous process or a pleurisy develops, the greater immobilization with the lesser ventilation on the side on which the diaphragm has been paralyzed may have undesirable results. Moreover, it is inadvisable to combine unilateral phrenic exeresis with pneumothorax on the other side, for even if the pneumothorax is small the limits of the necessary ventilation are readily surpassed. For these reasons the author advises that phrenic exeresis be used more sparingly and that temporary crushing of the nerve be employed instead.

Successive Exacerbations in Miliary Tuberculosis—Loeschke says that various clinical manifestations, particularly ophthalmoscopic observations and the fever curve, seem to indicate that miliary tuberculosis develops in successive crops. It was his aim to determine these successive exacerbations in pathologic-anatomic studies on cadavers and then to attempt to find them in the clinical histories. The similarity of two tubercles does not necessarily imply the same age. The degree of caseation seems to be more or less dependent on the age; however, newly caseating homogeneously appearing foci differ from old, friable caseations. Not every tubercle goes through all the stages of development, for instance, a predominantly fibrous tubercle may later again become exudative.

A direct comparison between the foci in different organs is likewise not permissible, for there doubtless exists in tuberculosis a more or less pronounced organic predisposition, the liver has a tendency to develop productive foci, whereas the adrenals are predisposed to caseation. Nevertheless, in organs of the same circulatory region, such as liver and spleen, a certain uniformity can be observed. If different types of foci are discovered in the lung and in the sphere of the systemic circulation, this does not necessarily imply different ages of the foci, for the doses of bacteria differ widely in both cases. In the lung, the possibility of bronchogenic older disseminations must be considered, only if the dissemination of the older foci is quite uniform can it be assumed that they are of hematogenous origin. For this reason the foci in other organs are of greater value for the detection of successive crops than are those in the lung. Among fourteen cases of generalized, hematogenous tuberculosis, the author found five in which traces of older hematogenous crops could be found. These older disseminations had taken place months or even years before. In the course of milary tuberculosis, successive crops may be determined by ophthalmoscopic observations. However, these cannot be definitely differentiated in the histologic picture. In some of the cases it was clear that the disseminations were of short duration. It seems that for the development of a milary tuberculosis not only the large bacterial dose is important but also the sudden and simultaneous dissemination of toxins that impair the capillary walls and thereby favor the dissemination in the tissues.

Prospects of Gonorrhea Therapy with Alpha Rays—To determine whether the application of the bactericidal alpha radiation has prospects of success in the treatment of acute gonorrhea, Nagell and Noethling investigated what quantities of alpha rays are necessary for the killing of gonococci in vitro. They found that in case of unilateral irradiation of surface cultures from 4 to 60 alpha particles have to be applied to each square micron. In case of fluid mediums and irradiation from all sides it is necessary that each cubic micron of culture medium absorb from 0.01 to 0.4 alpha particles. If about 6 per cent of an alpha particle is absorbed per cubic micron it may be expected that 80 per cent of the organisms are killed. If thorium X solutions are employed, slightly higher values are found. The authors conclude that ointments which contain from 0.02 to 0.2 millicurie of radon per cubic centimeter should produce some practical results, provided they act several hours each day.

Lesions Caused by Bucky's Irradiations—Kalz shows that the original contention of Bucky, that severe cutaneous injuries are impossible in the treatment with the extremely soft rays, has only been partly realized. To be sure, there are no severe cutaneous injuries, like roentgen ulcers, but mild atrophies have been observed repeatedly. These atrophies may be accompanied by pigmented spots or by vitiligo-like loss of pigmentation or by telangiectases. The clinical aspects vary according to the quality and quantity of rays and according to the localization. The author reports several cases of his own observation. In two cases in which irradiations were applied for naevus flammeus, telangiectases developed. Irradiation of a carcinoma was followed by thinning of the skin and depigmentation. The appearance of lentigo-like pigmentation seems to involve a predisposition, for the author observed it in a boy in whom comparatively mild doses had been applied to a naevus flammeus. On the basis of these and other observations the author concludes that in borderline rays, as in the harder roentgen rays, the dosage must be carefully watched. Depending on the quality of the rays and the localization, certain doses cannot be exceeded if impairments are to be avoided.

Vitamin A in Urine a Prognostic Sign—Boller and his associates studied in 321 patients with various disorders the vitamin A elimination in the urine before and after parenteral tolerance tests with a vitamin A preparation. The reactions were nearly always the same before and after the vitamin A tolerance test. It may be assumed that the parenteral administration is necessary only in rare cases, namely, when food is refused or when disturbances in the intestinal resorption may be assumed. Vitamin A is found in the urine in case of icterus with complete closure of the bile duct, in chronic nephritis and nephrosis and in lobar pneumonias before the critical defervescence. In severe cases of hepatic cirrhosis the urine always gives a positive vitamin A reaction, however, it is impossible as yet to detect a definite relationship between the severity of the disorder and the elimination of vitamin A in the urine. The authors assume that vitamin A is eliminated in the urine when both liver and kidney are impaired or when the impairment of one of these organs is so considerable that the other organ becomes likewise involved. By the administration of aminopyrine it is possible to reduce the elimination of large amounts of vitamin A in the urine or completely stop the elimination of small amounts. The determination of the elimination of vitamin A in the urine is of diagnostic value in hepatic and renal diseases. Regarding the prognostic value of the test, the authors say that, on the basis of their experiences, the elimination of vitamin A in the urine must always be regarded as an extremely serious sign.

Sugar and Cholesterol in Blood After Resection of Thyroid—Atnan and his collaborators found that after operations on the thyroid the postoperative increase in the blood sugar (in contradistinction to the majority of operations in other locations) takes a peculiar course. The hyperglycemia decreases, not as otherwise after from three to five hours, but shows a tendency to remain increased for a considerable period (frequently for twenty-four hours) or to increase again repeatedly. This characteristic behavior is dependent neither on the type of the anesthesia nor on the type of the thyroid disorder. It is assumed that the prolonged hyperglycemia might be explained as the result of the surgical trauma, by which large amounts of thyroid secretion are probably forced into the blood, and the peculiar increase in temperature, frequent perspiration, tremor and tachycardia may be due to this same factor. The result of studies on the cholesterol content of the blood before and after the operation seems to confirm this assumption. It was found that after operations on the thyroid the cholesterol content of the blood decreased much more than after other operations. The iodine content of the blood was determined in two cases after a surgical intervention on the thyroid and it was found that the values had almost doubled. The authors think that this too seems to indicate a postoperative increase in thyroid secretion following operations on the thyroid.

PRESENT-DAY STATUS OF THE TREATMENT OF NEUROSYPHILIS

CHAIRMAN'S ADDRESS

PAUL A O'LEARY, M D

ROCHESTER, MINN

The treatment of syphilis of the central nervous system is still in a developmental phase. We have passed through the trial era of specific treatment and have now had sufficient experience with nonspecific measures to crystallize our concepts of their therapeutic value. In appraising the results of treatment I have followed the classification of neurosyphilis (given in the accompanying table) adopted by the Committee on Nonspecific Therapy of Neurosyphilis.¹

ASYMPTOMATIC NEUROSYPHILIS

The report² of the Cooperative Clinical Group shows that the results of treatment of asymptomatic neurosyphilis are less encouraging than the reviews of smaller groups of cases had indicated. The survey indicates that the results of treatment are dependent on the severity of the spinal fluid reaction as well as on the type and amount of treatment administered after the diagnosis of asymptomatic neurosyphilis has been made.

The incidence of asymptomatic neurosyphilis is twice as common in early as in late syphilis (24.5 per cent versus 12 per cent in white adults), and the response to treatment is, on the whole, more satisfactory in the early groups because the majority of the patients manifest the less malignant types of spinal fluid. The use of combined³ treatment reversed to negative the milder

types of positive spinal fluids in 84 per cent of the cases, while in only 45 per cent of the cases in which the condition was of severe grade (paretic formula) did the spinal fluid become negative.

When the results were appraised according to the system of treatment employed, it was found that the routine use of arsphenamine, bismuth compounds and mercury reversed 75 per cent of the spinal fluids to negative and that these remained negative for ten years after treatment. When the routine treatment was augmented by intraspinal therapy in the resistant cases 74 per cent of the spinal fluids were still negative ten years after treatment. The use of routine therapy and tryparsamide caused a reversal to negative in 68 per cent of the spinal fluids in a similar group in which routine treatment alone had failed. After a period of observation of ten years these spinal fluid reactions were still negative for evidence of syphilis. Malaria therapy when given to a group of patients in treatment of whom chemotherapeutic measures had failed, resulted in negative reactions in the spinal fluid in 26.5 per cent of the cases, these negative reactions were maintained for ten years.

When the 565 cases of asymptomatic neurosyphilis were grouped together and all measures of treatment were appraised, it was found that satisfactory serologic reversal was produced and maintained in 64.4 per cent of the cases. Clinical progression was noted in 6 per cent of the cases of this type of neurosyphilis even though treatment with all of the various modalities was continued. Simpson⁴ reported that combined artificial fever and chemotherapy reversed the serologic characteristics of the spinal fluid in six of the seven cases of asymptomatic neurosyphilis in which he administered treatment and which he observed for two years.

MENINGEAL NEUROSYPHILIS

The results from the treatment of a large group of patients with meningeal neurosyphilis have not as yet been subjected to detailed study. The reports in this country, by Moore⁵ and by Stokes,⁶ show that clinical improvement occurs in from 80 to 85 per cent of cases. The majority of these patients show a satisfactory response to the routine types of treatment because the clinical response is usually striking and the marked pleocytosis as a rule, decreases rapidly. Meningeal neurosyphilis in which the clinical symptoms are pronounced is sometimes difficult to distinguish from dementia paralytica, and when the latter complication is present the results of routine treatment are unfavorable.

3 Routine treatment consists of the use of one of the arsphenamines in conjunction with a heavy metal either bismuth or mercury. If mercurial injections are used one week of injections (six rubs) is considered equivalent to one injection of mercury. Routine treatment was given either intermittently or continuously with compounds of bismuth or mercury administered simultaneously with or in the intervals between the courses of arsphenamine. Intraspinal therapy is carried out by drawing 50 cc of blood from the patient half an hour after he receives an injection of one of the preparations of arsphenamine. The serum thus obtained is inactivated at 37 C and injected into the spinal canal after withdrawal of an equal amount of spinal fluid. Tryparsamide therapy consists of ten injections to a course given concurrently with injections of a bismuth compound. A rest period of two months is permitted between the courses. In malaria therapy from twelve to fourteen bouts of fever were originally allowed each patient while now eight or nine such febrile reactions are considered sufficient. Combined treatment comprises the foregoing methods of treatment used either successively or concurrently.

Eight patients who came under my care with evidence of meningeal neurosyphilis and to whom I gave malarial treatment because their spinal fluids retained a paretic formula in spite of specific treatment obtained completely negative serologic results three years after the fever treatment. Routine and intraspinal treatment was given to all these patients following malarial therapy. In three cases in which neurovascular accidents developed while the patients were receiving treatment with arsphenamine (neurorecurrence or

Classification of Neurosyphilis

- 1 Asymptomatic *Subjective*—no symptoms
Objective—positive spinal fluid
- 2 Meningeal A *Subjective*—fever chills weakness headaches nausea vomiting dizziness diplopia fatigue nervous exhaustion
Objective—positive spinal fluid deafness choked disks stiff neck meningismus nerve palsies aphasia reflex changes convulsions delirium coma
B Nerve palsies which appear with onset of 'secondaries' before antisyphilitic treatment is started are diagnosed as meningeal neurosyphilis
- 3 Vascular *Subjective*—headaches dizziness
Objective—Spinal fluid may be negative or positive. Mild personality changes mental dullness convulsions hemiplegia aphasia recurrent cerebrovascular accidents evidence of arteriosclerosis usually absent
- 4 Meningovascular The meningovascular group is made up of those cases of neurosyphilis lacking the characteristic manifestations which warrant a diagnosis of tabes dorsalis dementia paralytica vascular or meningeal neurosyphilis but manifesting evidence that is a combination of meningeal and vascular components whether occurring early or late in the course of the syphilis ('early' and 'late' referring to the duration of the syphilis). Spinal fluid usually positive
- 5 Optic atrophy Primary as with tabes dorsalis or secondary to neuroretinitis and so on
- 6 Neurorecurrences If nerve palsies appear after treatment is started exclusive of hemorrhagic encephalitis the diagnosis should be neurorecurrence or relapse. If it develops before treatment is started it is to be diagnosed as meningeal or meningovascular syphilis depending on the degree of involvement. If palsy develops within the first two years of infection as a result of lapse in treatment the diagnosis is neurorecurrence whereas if it develops while the patient is on treatment it is diagnosed as progress of the disease and is classified according to the type of involvement
- 7 Dementia paralytica *Subjective*—Nervousness depression fatigue decreased libido decreased potentia nymphomania vertigo irritability bradyphrenia changes in weight changes in memory disturbances of sleep
Objective—Personality changes conduct change mental deterioration emotional instability loss of memory disorientation poor judgment mental confusion dysarthria writing disorders grandiosity euphoria irritability excitability tremors (of face particularly), deep reflexes hypoactive or hyperactive pupillary changes convulsions cerebral accidents transient salivation care less dress slovenliness
- 8 Tabes dorsalis *Subjective*—Diplopia neuritic pains reduced libido and potentia gastro intestinal crises paresthesia of hands feet and trunk headaches dizziness
Objective—Argyll Robertson pupils fixed pupils anisocoria reduction of deep reflexes ataxia reduced sense of pain hyperesthesia changes in perception of heat and cold incoordination failing vision hemianopia optic atrophy vibratory sense changes Charcot joints gastro intestinal crises incontinence trophic ulcers cerebral nerve palsies
- 9 Other types Include all the rare manifestations in some of which the syphilitic origin is disputable such as Parkinson's disease multiple sclerosis myelitis spastic paraplegia chronic polyomyelitis brain tumors epilepsy

recidive) the results from combined fever and chemotherapy, which was given immediately after the appearance of the palsies were excellent. I also have observed patients with early syphilis complicated by neurosyphilis, the malarial treatment of whom produced a decided reversal in the reaction of the spinal fluid but did not prevent recurrence of cutaneous lesions and lesions of the mucous membranes. Accordingly, in cases of early syphilis complicated by the more severe types of neurosyphilis, if fever therapy is used it must be given in conjunction with, or followed immediately by, intensive chemotherapy.

MENINGOVASCULAR NEUROSYPHILIS

The results of treatment of disseminated meningovascular neurosyphilis by chemotherapeutic methods are also encouraging when the treatment is given shortly after the appearance of the clinical symptoms. Wile and Davenport⁷ reported striking clinical improvement in twenty of twenty-four cases in which malarial therapy was administered. Meningovascular neurosyphilis may be a transient phase of the disease, recognized while the patient is in the process of developing the more advanced clinical types of involvement of the central nervous system. Accordingly, if the clinical and serologic response to treatment is slow, consideration should be given to the possibility that clinical progression is occurring. Experience has revealed that chemotherapy after the fever treatment augments the results, both clinical and serologic, in meningovascular neurosyphilis.

VASCULAR NEUROSYPHILIS

In cases of the vascular type of neurosyphilis in which other causes of neurovascular accidents have been excluded, the results of treatment from specific medication are none too encouraging. The hazard of fever therapy is great if patients present this complication. It should be borne in mind that, in most of the cases in which the paralysis is of transient nature, dementia paralytica is the cause of the cerebrovascular accident rather than pure vascular neurosyphilis. The prolonged use of chemotherapeutic agents in small doses, and potassium iodide, is recommended for patients with vascular neurosyphilis.

DEMENTIA PARALYTICA

Arsphenamine, bismuth and mercury when used alone have but little value in the treatment of dementia paralytica, hence the discussion of the treatment of this type of neurosyphilis will be limited to shock therapy, of which chemotherapy is an essential part. Malarial therapy produced clinical remissions to the extent that 35 per cent⁸ of my patients whose disease had progressed far enough to warrant institutional care at the time treatment was given were still able to work ten years after treatment. Dattner⁹ noted that the so-called economic remission had been maintained in 38 per cent of his cases ten years after fever therapy. Of the patients who present incipient evidence of dementia paralytica, from 50 to 85 per cent will have economic remissions, this result depends on the degree of cerebrovascular involvement, the type of dementia paralytica, the grade of the spinal fluid reaction, the duration of the syphilis, and the amount of previous antisyphilitic treatment. Experience with fever therapy indicates that the best results from it are noted in the cases in which there are no clinical signs of dementia paralytica but in which the paretic formula in the spinal fluid is maintained in spite of intensive treatment with the specific remedies. Accordingly, I⁸ still believe that malarial therapy is of more value in the prevention of dementia paralytica than it is in the treatment of it.

The results from treatment with the various mechanical units for producing fever are similar to those from

7 Wile U. J. and Davenport K. M. The Malarial Therapy of Neurosyphilis, Other Than Uncomplicated Dementia Paralytica. *J. A. M. A.* 97: 1579-1585 (Nov. 28) 1931.

9 Dattner Bernhard. Moderne Therapie der Neurosyphilis mit Einschluß der Punktionstechnik und Liquor Untersuchungen. Vienna Wilhelm Maudrich 1933.

malarial therapy Neymann¹⁰ recently reported that in 22 per cent of approximately 700 cases of dementia paralytica, collected from various reports in the literature, economic remissions developed. Bainacle, Ebaugh and Ewalt¹¹ treated and compared two series of patients with dementia paralytica, one group received hyperthermy and tryparsamide and the others were given malarial therapy only. The incidence of remission was 6 per cent higher in the group treated with the combination of hyperthermy and tryparsamide. No doubt the addition of tryparsamide in the group treated with malaria would have equalized the results. Irrespective of the type of fever therapy used, chemotherapy should be started shortly after the febrile course. The combination of tryparsamide and bismuth has offered the highest incidence of remissions among patients with dementia paralytica when used following fever therapy.

TABES DORSALIS

It is difficult to appraise the results of the treatment of tabes dorsalis not only because it is such a multiform disease but also because it may spontaneously arrest itself or show a persistence of symptoms, even though clinical progression has been stopped, and because the results of serologic studies are inconsistent and do not always parallel the clinical observations.

I shall discuss, first the serologic results of treatment. The outstanding serologic reversals among patients with tabes dorsalis are noted in those cases in which the signs indicate that the tabes is mild and incipient and in which the syphilis has been present ten years or less. Likewise, the patients who have the milder types of spinal fluid positivity obtain serologic reversal with smaller amounts of treatment and with less intensive therapeutic methods. In a study of cases of tabes dorsalis it was found that serologic reversal was obtained from chemotherapy in 64 per cent of 630 cases. In cases in which the spinal fluid changes were those of the mild type of the disease, the reversals of the serologic reaction to negative were almost twice as common (81 per cent) as in those in which the fluids were those of the more malignant type of the disease (46 per cent). An appraisal of the value of any therapeutic measure used for the treatment of patients with tabes dorsalis is difficult because the method of treatment is usually intensified when the serologic characteristics or the clinical symptoms are resistant. Accordingly, the attempt to evaluate the more intensive systems of treatment is, in reality, an index of the status of the patient's resistance to the infection rather than an actual evaluation of the system of treatment. This was well demonstrated when the results of adequate and inadequate amounts of specific treatment were appraised, as it was found that the incidence of serologic reversals was about the same from the two types of treatment. However, in at least two thirds of the cases the early reversal of the spinal fluid indicates that a favorable clinical response will be noted. From all methods of chemotherapy I found that excellent clinical results were obtained in 26 per cent of the cases of tabes dorsalis, moderate improvement developed in 41 per cent and in 22 per cent there was no change. In 11 per cent the disease progressed clinically in spite of treatment. An

appraisal of the clinical results obtained from the various systems of treatment indicates that the addition of intraspinal therapy to routine chemotherapy will double the number of patients who show marked improvement. In fact, among patients with the early clinical signs of tabes dorsalis the use of the combination of intraspinal and routine therapy produced the greatest proportion of maximal improvement. The results from the use of tryparsamide and bismuth compounds were slightly less than those from intraspinal therapy. The patient with advanced signs of tabes dorsalis responds but slightly, or not at all, to the various methods of treatment.

Malarial therapy produced clinical arrest in 26 per cent of my cases of tabes dorsalis in which routine treatment had failed and was of material help in an additional 40 per cent. Malarial therapy was of benefit to 31 per cent of patients with gastric crisis, and improvement occurred in 11 per cent of those with persistent lightning pains. In 14 per cent of the cases of optic atrophy, apparent arrest of the loss of vision developed following malarial therapy. Bennett,¹² reporting on the results of hyperthermy, noted that eleven patients with these resistant complications of tabes were greatly improved. It would seem advisable to postpone further judgment on the results of hyperthermy in cases of this type until a period of observation of several years has elapsed, because I noted comparable results in a similar group of cases the first year after malarial therapy, following which the symptoms reappeared.

Among patients with tabes dorsalis and completely negative serologic characteristics of the blood and spinal fluid, the results from treatment of all types have been disheartening. Lightning pains, gastric crisis, optic atrophy, ataxia and Charcot joints are not materially benefited by fever or chemotherapy if the examination of the spinal fluid gives negative results. The surgical treatment of gastric crisis, lightning pains and Charcot joints has not been entirely successful, and the variations in the results from surgical measures would indicate that the skill of the surgeon must be outstanding if success is to be met.

Tryparsamide has well withstood the test of time. Since Lorenz and his co-workers¹³ recommended its use in the treatment of dementia paralytica in 1923, the therapeutic value of the drug has steadily increased. Reese¹⁴ observed that results from the use of tryparsamide in dementia paralytica compare favorably with those from fever therapy. The drug is valuable also in the treatment of such manifestations of neurosyphilis as tabes dorsalis, meningeal neurosyphilis, meningovascular neurosyphilis and some of the rare types of neurosyphilis. In fact, tryparsamide can be used to advantage in treatment of any of the late manifestations of neurosyphilis, provided the patient does not present evidence of disease of the optic tract. It has special merit in the treatment of late neurosyphilis following fever therapy. Tryparsamide should not be used in the treatment of early cardiovascular syphilis or latent syphilis with persistently positive serologic characteristics of the blood.

Potassium iodide is still given liberally and over long periods in the treatment of neurosyphilis, even though its use is empirical.

Many agents have been recommended for the treatment of neurosyphilis other than those I have mentioned. A few of these which still have enthusiastic advocates are silver arsphenamine, sulfur,⁹ typhoid vaccine,¹⁶ bacterins,¹⁶ and hot baths.¹⁷ The results of treatment with these agents have been less satisfactory than those I have discussed, although an occasional patient may be encountered in which one of these agents is of definite value. In the selection of the type of chemotherapy that is to follow fever therapy, attention should be paid not only to the type of neurosyphilis but also to the other complications of syphilis which the patient may manifest. For example, in the presence of dementia, tryparsamide is recommended, when simple aortitis without regurgitation is recognizable, arsphenamine, and bismuth or mercury compounds, may be of special merit, while in the resistant types of asymptomatic neurosyphilis I have found that the use of intraspinal therapy results in the highest incidence of reversal of the serologic characteristics of the spinal fluid.

SUMMARY

The development of knowledge of neurosyphilis and its treatment dates back a quarter of a century. During this time it has been shown that one of the outstanding values of chemotherapy, with arsphenamine and compounds of bismuth or mercury, is its ability to prevent the development of neurosyphilis. Of a large group of cases of early syphilis, adequate administration of these remedies prevented the appearance of neurosyphilis in 94 per cent. When the neurosyphilis was manifested, the value of chemotherapy was greatest in the asymptomatic type, in which it produced excellent results in 75 per cent of the early cases, while it was practically valueless in the treatment of patients who gave evidence of well established dementia paralytica. Between these two extremes are a great number of patients with various types of neurosyphilis, in which the results of chemotherapy differ according to the duration of the syphilis and the degree and extent of involvement of the central nervous system. In those cases in which only invasion of the nervous system has occurred the results of treatment are usually satisfactory, while in those in which extensive parenchymatous and vascular involvement has occurred the results are proportionately unfavorable. Accordingly, the demand for a method to control the disease in the later types was met when Wagner von Jauregg¹⁸ recommended malarial therapy, which also has weathered the trial of time and experience in thousands of cases. The effort to simplify malarial therapy resulted in the development of artificial fever therapy, first by the radiotherm, then by the hypertherm, and subsequently by a variety of means of raising the patient's temperature. It was at first hoped that the production of fever by mechanical methods

would result in a new method of therapy, namely, the killing of bacteria within the patient. Experience to date has shown, however, that this concept is applicable only in those diseases in which the thermal death point of the bacteria is low. *Spirochaeta pallida* has a high thermal death point (114 F), so it would appear that the favorable results obtained in neurosyphilis by fever therapy, whatever the type may be, are the result of some biologic phenomenon the nature of which at present is not known. Fever therapy in the treatment of neurosyphilis, although used empirically, should be administered in conjunction with, or immediately followed by, chemotherapy.

In addition to arsphenamine, compounds of bismuth or mercury, and fever therapy, there are several other therapeutic agents which have been shown by years of experience to be of value in the treatment of neurosyphilis. Outstanding among these is tryparsamide, which, when used in conjunction with fever therapy, offers the highest incidence of clinical and serologic remissions in dementia paralytica. The combination of tryparsamide and a compound of bismuth is recommended in the treatment of patients with neurosyphilis who are too debilitated to undergo fever therapy, as well as in the types of neurosyphilis in which benefit does not result from fever therapy.

The value of intraspinal therapy is well demonstrated in cases in which there are early clinical signs of tabes or optic atrophy, and in cases of asymptomatic neurosyphilis. Intraspinal therapy should not be given when evidence indicates extensive involvement of the lower part of the spinal cord.

The less intensive types of nonspecific therapy, such as those in which are employed typhoid vaccine, hot baths, sulfur in oil, and bacterins, are applicable in those cases in which a mild nonspecific effect is desired, because in the malignant types of neurosyphilis these remedies are less efficient than the more strenuous types of fever therapy.

In addition to the use of the specific and nonspecific agents in cases of neurosyphilis, attention also must be directed toward the care of the complications of neurosyphilis, such as infected cord bladder, moreover, the development of drug addiction should be avoided.

As the treatment of neurosyphilis cannot be standardized, the treatment of the patient who has syphilis of the nervous system must be individualized. Many of these patients, especially those with the early manifestations of neurosyphilis, are strikingly improved by routine therapy, and it is advisable to give them, first, the benefit of a trial with arsphenamine and a bismuth or mercury compound. If there is not a favorable response after two such courses of treatment, the need for nonspecific therapy then should be considered. However, if the patient is displaying early manifestations of dementia paralytica, fever therapy should be employed immediately. The factors that influence the decision as to the type of nonspecific treatment to adopt are the type and degree of neurologic involvement, the age of the patient, the duration of the syphilis, and the status of the patient's general condition. Fever therapy, irrespective of the type used, must be given in conjunction with, or it must be followed by, chemotherapy. The earlier the neurosyphilis is recognized and the treatment started, the more favorable will be the effects of any type of therapy.

INDUSTRIAL PREVENTIVE MEDICINE

A PLAN FOR THE CONTROL OF OCCUPATIONAL DISEASES

C D SELBY, M D

DETROIT

Physicians in industry devote much attention to the prevention of disease. They know that diseases of occupational origin are amenable to control and they understand the technique, but their services are available to a limited section of the working population, mostly in large establishments. Physicians in general practice, who are not so familiar with the subject, serve the large remainder. They can now well afford to give the subject consideration.

The time is coming, if it is not already here, when the managements of small plants will seek medical advice on the effect of shop conditions on health and will request guidance in giving their employees medical protection. Naturally, they will go to the doctor whom their workmen consult, and this is the physician in general practice. This elemental presentation in outline form is prepared chiefly for him.

For discussion, the program of industrial preventive medicine may be divided into three sections: the prevention of occupational diseases, the maintenance of health, sometimes known as physical supervision, and the rehabilitation of workmen disabled by injury, sickness or age.

A PREVENTION OF OCCUPATIONAL DISEASES

To prevent occupational diseases one must seek out their sources and control them. These will be found in working conditions and environment in processes, operations or methods and in substances or materials intrinsic to manufacturing. They are usually in the form of dusts, mists, vapors, fumes, gases or fluids. For the purpose of brevity, all industrial sources of disease are termed "exposures," and the word will be used in that sense throughout this article.

1 *Identification of Exposures*—The first step then, toward control is to identify the materials or conditions that are capable of causing disease. This can be done by (a) tracing back sicknesses that occur, which is the usual method, though it is unscientific and expensive. It is far better for the doctor to anticipate possible diseases by (b) a study of the materials used in manufacturing. If any of them are recognized as possible sources of disease, the operations or processes of which they are part are immediately recognized as exposures. Most sources of disease can be located in this way, but it is also important that the physician bear in mind that a harmless substance may become a source of disease under certain conditions. It is therefore necessary that the doctor (c) study the methods of manufacturing and that he look for additional causes in the (d) general plant conditions.

2 *Determination of Importance of Exposures*—Exposures having been identified, it is the doctor's duty to determine their importance. This he may do by (a) casual observations. Harmful dusts, fumes, mists, vapors and gases which are noticeable are obviously not under control. If the doctor has any doubt, or if for any other reason he desires scientific confirmation, he may arrange for (b) engineering studies consisting of dust counts and other analytic methods of deter-

mining the condition of air at the breathing level of the workmen. These will indicate the extent of exposures, and the results may become useful as factual evidence. Such studies can be made by an industrial hygienist, by a plant chemist in cooperation with the physician or by some one especially trained for that purpose, not necessarily a chemist or an engineer. If dust and other contaminants are important problems, a more or less continuous engineering service is desirable because conditions vary from time to time and one reading does not necessarily reflect the average.

3 *Control of Exposures*—This is largely a ventilation problem. It is not the duty of the physician, but after he has identified sources of disease and reached conclusions as to their importance, it becomes his duty to direct the management's attention to the need of control measures. How he does this depends on his place in the organization.

For information, however, it may be said that exposures are ordinarily controlled by (a) substitution of harmless materials if possible, (b) changes in processing and manufacturing, (c) capture of dusts, fumes, mists, vapors and gases at their points of origin, (d) segregation of operations in which capture is not feasible, (e) use of respiratory protective devices when safe limits of air contamination are necessarily exceeded or, (f) if the exposure is dermal, the use of protective creams or suitable gloves and clothing.

4 *Maintenance of Control*—Exhaust systems for the removal of dust and other air contaminants, and all respiratory protective devices, being mechanical in nature, are prone to get out of order. Plant conditions and methods may be changed. It is therefore essential that a plan for the prevention of diseases in industry include procedures that assure continued control over exposures. The first essential is intelligent use of the protective equipment. Workmen must receive (a) suitable instruction and have (b) watchful supervision.

In order that the plant physician can make his full contribution to the promotion of a control program, it is advisable that he make (c) periodic plant inspections, the periodicity of which is determined by the conditions which he finds. It may be necessary for him to visit some departments weekly, others monthly.

Because of frequent changes in manufacturing methods and processes, it is also important that the doctor make (d) studies of all materials that are purchased and also (e) studies of all new processes or modifications of old ones before installations are made or changes are effected.

Application of this program serves to simplify the problem of preventing occupational diseases and enables the plant physician, or the physician who practices casually in industry, to make an understandable analysis for submission to the management.

Many conditions capable of causing disease will be found to be under control. As a matter of fact, industry has progressed surprisingly in this direction, far more than members of the medical profession realize. Some exposures will be on the border line, and a few will need urgent attention. The practical approach is to secure early control of those most needing attention, after which exposures on the border line of importance may be corrected.

B MAINTENANCE OF HEALTH

When the physician has secured control over the conditions in the plant which are capable of causing disease, his health maintenance program is considerably simplified but it is nevertheless important that he give the

workmen themselves enough of his attention to assure them early diagnosis of diseases that may occur despite measures to control exposures. This attention consists of physical examinations designed to assist workmen to find suitable employment, to remain suitably employed and to safeguard their health during employment.

1 *Preemployment Examinations*—The preemployment inspection which has become an established custom is not adequate to the purpose of a complete health maintenance program. The examination should be sufficiently complete for accurate diagnosis. It is important, for example, that a man with active tuberculosis not be employed in a dusty occupation. Such employment would be unfair to the applicant himself and to his fellow workmen. Such a man needs treatment, not employment.

It is not possible to recognize tuberculosis in all the stages by physical examination alone, therefore, modern industrial preventive medicine furnishes an applicant for employment in a dusty occupation with an x-ray examination of the chest. This thought being carried a little further, the examination should be so complete as to permit the physician to advise the employment department as to placement of applicants who are physically handicapped. Heart disease, by way of illustration, may on first impulse call for rejection, but physicians know that many men with cardiac lesions may be employed under suitable conditions and given opportunities for useful lives. To see that the physically handicapped are suitably employed is an important function of medical service in industry.

Many examples of this nature could be mentioned, but it is not my purpose to set up standards for rejection or placement. The doctor must use his judgment. He must decide each questionable case on its merits, and his decision must be influenced by facts only. Naturally, his examination should be of such completeness as to justify his decision. To this end, special diagnostic equipment may be needed—x-ray apparatus for the study of the lungs, laboratory facilities for studies of the blood, an electrocardiograph and other apparatus.

The object of the preemployment examination is to permit acceptance of applicants with a minimum of risk to themselves, their fellow employees and their employers and placement under conditions that will have the least possible harmful effects on their health and earning power.

2 *Periodic Examinations*—The purpose of the periodic examination is to assist workmen to continuous employment with a minimum of physical deterioration or sickness attributable to occupation. As some workmen are susceptible to certain exposures, it is desirable that all new employees who may in any way be affected by their occupation be observed frequently during their early days of employment. All workmen should be examined as often as necessary to assure them against ill effects.

The frequency of the periodic examination depends on the physical condition of the workmen at time of employment or at time of last examination and on the nature of their occupations. If they are employed where lead is used under conditions which indicate the possibility of absorption, they should be examined monthly. If they are exposed to dust of a silicious nature or otherwise, they should be examined once a year. All workmen absent more than seven days because of injury or sickness should be examined on returning to work. All employees should be examined at least once a year.

If the doctor finds conditions that indicate the need of changing a man's occupation or of recommending a period of absence for recovery, he should be certain of his ground before he renders a decision, but, when he has once reached a conclusion, the decision should be final, always assuming, however, that it has been based on an impartial study of the medical facts as he sees them.

3 *Consultations*—The established plant physician, having won the confidence of the employees, will be consulted frequently for the relief of minor ailments and for advice on the treatment of conditions that may or may not have relation to occupation. This is a delicate phase of industrial practice. The doctor must so conduct himself as to retain the confidence of the workmen and maintain the good will of the workmen's own private physicians. The doctor in industrial practice must not compete with physicians in general practice. It is possible, however, for him to shorten the period that ordinarily exists between the early stages of sickness and treatment by the family physician.

One of the most important duties of the plant physician is to guide the workmen desiring or needing general medical service outside the plant. He may give temporary treatments which will enable workmen to finish a shift, he may treat injury and sickness that result from occupation, but all else must be directed into the channels of ordinary medical practice.

This phase of industrial medicine is highly regarded by the management as a builder of good will. It is valued accordingly. It rounds out the plant physician's health maintenance program, it behooves him to encourage it.

4 *Adequate Treatment*—The physician is a professional man. He is entitled to use his judgment in the treatment of injuries and diseases, but he does not need to invade the field of private practice on the theory that it is necessary for him to do so in order to protect the interest of the management or guarantee workmen adequate treatment.

5 *Records*—The maintenance of suitable and adequate records is one of the most difficult problems confronted by the physician in industry. Ordinarily his records show volume of work. The management is not particularly interested in records of this nature. But the management does want records which will indicate sources of injury and disease which are not under control. The management also wishes a complete medical record of each employee in order that claims for compensation may be judged fairly, and the physician certainly needs a record of this nature in order that he may advise workmen in the maintenance of their health.

Industry has little conception as to the cost or importance among workers of ordinary sickness not attributable to occupation or of the possible relation, if there is any, of occupation to ordinary sickness. Here is an opportunity for the plant physician to make a special study. It is therefore suggested that medical records be such that studies can be made of ordinary sickness as well as of occupational diseases and injuries. This is important because the range of compensatable diseases is gradually being extended.

C REHABILITATION

1 *Physical Therapy*—This is mentioned chiefly for the purpose of indicating its place in a health maintenance program. If workmen are disabled because of sickness or injury, it may be possible for the physician

to ameliorate their disabilities by special surgical treatments or physical therapy

2 Occupational Therapy—When the physician has gained the best possible physical condition for disabled workmen, the final results may require changes of occupation and possibly special training. These are not medical functions, but they should be of interest to the physician

3 Replacement—Reconstructive surgery, physical therapy and retraining of disabled workmen are all more or less useless unless such workmen can be given work suitable to their changed physical conditions. This is an employment procedure, but it requires the highest degree of cooperation between medical and employment departments and skilful handling

The purpose of rehabilitation is to conserve human values. The same motive is applicable to industrial preventive medicine, and by that token the physician who serves the working people impartially serves industry best. He must serve them as he would if they were his private patients. Good will is an unsought but welcome result of such a policy, and it might readily become the most important output of a plant medical department

General Motors Corporation

ABSTRACT OF DISCUSSION

DR G H GEHRMANN, Wilmington, Del. Our knowledge of occupational diseases is extremely meager. There are undoubtedly many occupational diseases which have not been detected up to the present time. Our knowledge of the action of compounds on the central nervous system and the circulation is almost negligible. Any plan for the control and prevention of occupational diseases must be based on an understanding of the toxicology of the compounds involved. It is essential to know what organs are attacked and the mode of entry into the circulation. From this the symptomatology is deduced, which enables one to set up an examination schedule adequate for the detection of absorption of that particular material. Pre-employment examinations should be for the purpose of selecting individuals who can safely work in chemical industries without being subjected to the danger of aggravating an existing condition. Periodic examinations are of little use as such, unless they are based on the toxicology of the compounds involved and a knowledge of how rapidly the compound is absorbed into the circulation. Periodic examinations must be of a special type and general physical examinations in most instances fail to reveal the desired information. When it becomes necessary to treat occupational diseases we have a true indication of failure in protective methods both from the mechanical and from the medical points of view.

DR ALVIN W SCHOENLEBER, New York. Dr Selby called attention to the evolution of industrial medicine. Only a few years ago the industrial physician was one who bandaged fingers. We have now reached the stage at which the industrial physician is recognized as one who occupies an important position in the control of occupational diseases. We are now well into the next stage of evolution, in which the industrial physician is recognized as a most important factor in preventive medicine. Public health officers are doing marvelous work in the control of disease by instituting measures that apply to the community rather than to the individual, their activities being limited largely to communicable diseases. There is, however, another great field for preventive medicine which cannot be touched by public health officials because it requires personal contact with each individual. I refer to periodic health examinations, which, if properly conducted, and suitable action taken in accordance with the conditions that are found, will reduce disability particularly from degenerative diseases, raise the general level of health and increase the employees working efficiency. The industrial physician, because of his special training and opportunities for contact with large groups of persons, is in an ideal position to practice this most important phase of

preventive medicine. Those of us who come in contact with the average workman know that the greatest obstacle to constructive preventive medicine of this type is the failure of employees to have defects corrected because they feel they cannot afford medical and surgical service except for conditions causing acute discomfort. For several years we have been threatened with social medicine. Industrial physicians are in accord with others in opposing government control of medical service, but we more than the general practitioner realize that there is a real need for a more satisfactory means of financing the cost of medical service. This, then, suggests the next step in the evolution of industrial medicine. The so called social or state medicine is in reality industrial medicine, because it applies only to employees and employers who can be taxed. The problem of providing more adequate medical service at a reasonable cost is therefore one which should be solved by industry with the guidance of the industrial physician. Industry has been slow to realize the danger of state medicine or to take practical steps to minimize this danger. It is not yet too late to adopt practical businesslike plans for providing employees with medical service at reasonable cost which, if successfully operated will counteract propaganda for state medicine.

DR HAROLD B WOOD, Harrisburg, Pa. There are a number of small plant physicians who never read *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*. I would suggest that the state health departments in their monthly publications print abstracts of this paper of Dr Selby's and also give a list of the deleterious substances which were presented to us by Dr McConnell, including the trade names, so that these physicians may know what the deleterious substances are. Another point I should like to mention is that a large industry using dyestuffs was having considerable trouble, getting many cases of dermatitis. On investigation it was found that the dyestuffs were those having the methyl radical. The industry switched over to dyestuffs using the ethyl radical and they have had no further trouble. That is a point for the consideration of those persons having the opportunity of investigating dyestuffs.

DR C D SELBY, Detroit. The discussion has emphasized a point which I have in mind, namely, that preventive medicine in industry is but one aspect of preventive medicine, but do not forget that we as industrial physicians have the workmen about forty hours a week now out of a total of 168 hours. They are in your hands the remainder of the week, so the problem of the maintenance of health of the working men is a public health problem. We of industry are prepared to assist public health officers and will carry on under their guidance. Industry wishes to give labor the best possible medical protection consistent with public interest, the interest of management, of labor and of the medical profession.

Connective Tissue and the Defense Reactions—The intensive study of various defense reactions has resulted in amassing more and more evidence substantiating the idea that the defense of the vertebrate body against invading parasites, or even against inanimate foreign material introduced parenterally, predominantly involves the connective tissue. The cells of this tissue arrive embryonically from the mesenchyme and in their widespread distribution throughout the adult animal comprise the blood and lymph, the reticular tissues of the myeloid and lymphatic organs, the loose connective tissue associated with the skin and various organs, the dense connective tissue as is found classically in the derma of the skin, the regular connective tissues of the tendons, ligaments, etc., the specialized connective tissues found in the mucous membranes of the gastro-intestinal tract and uterus and the interstitial connective tissue of the lung testis and ovaries. There various tissues perform widely diversified functions in the normal animal, varying from respiration, intermediate metabolism and storage, to mechanical support. The defense reactions, however, are largely limited to the cells and fluids of the blood and lymph and of the reticular and loose and dense connective specialized or accentuated aspects of such normal functions as intermediate metabolism and storage—Taliaferro, W H, and Mulligan, H W. *The Histopathology of Malaria, with Special Reference to the Function and Origin of the Macrophages in Defense*, part 1. Memoir 29, Indian Medical Research Memoirs, May 1937.

PURPURA HAEMORRHAGICA

WITH SPECIAL REFERENCE TO COURSE
AND TREATMENTMAXWELL M. WINTROBE, M.D.
EDWARD M. HANRAHAN, JR., M.D.
AND
CAROLINE BEDELL THOMAS, M.D.
BALTIMORE

Ten years after Kaznelson's¹ announcement of the dramatic results following splenectomy in a case of "essential thrombopenia," Whipple² was able to collect data concerning the effects of splenectomy in eighty-one cases. Spence³ collected twenty-three additional records, and in 1932 Eliason and Ferguson⁴ summarized a total of 213 cases. This number, however, did not represent the experience of any individual or group but was a compilation of reports by many writers, most of whom described only one or two cases, published within a year after splenectomy.

The course of purpura haemorrhagica is so varied, and spontaneous remissions, relapses and recurrence many years after the initial episodes of bleeding are so common, that it must be evident to those familiar with this disorder that adequate appraisal of the effects of operation makes necessary the study of patients many years after splenectomy. Furthermore the value of splenectomy can be determined only by comparison with the course of purpura haemorrhagica as treated by medical measures. Little information of this kind is available.

MATERIAL

Our report is based on the observation of sixty-two patients who had been seen in the Johns Hopkins and the Union Memorial hospitals in Baltimore. Nineteen⁵ of these patients were subjected to operation. The great majority were seen at some stage by us. They were selected only in the sense that doubtful cases were excluded. Typically, they presented the phenomena of abnormal bleeding or bruising or both, petechiae, diminished numbers of platelets, prolonged bleeding time, nonretractility of the blood clot, normal clotting time, positive reaction to the tourniquet test and, in the more recent cases a positive reaction to the moccasin venom test.⁶ Instances of purpura or hemorrhage asso-

ciated with leukemia, aplastic anemia, poisoning or infections such as bacterial endocarditis were not included in the series, or cases of the type of purpura associated with erythema, swelling or inflammation.

Thirty-six patients were reexamined by us, and information through reports of various physicians and of the patients themselves was obtained regarding all but six cases in this series. Data were thus collected regarding the course of thirteen patients from ten to twenty-nine years after their initial symptoms of purpura, nineteen patients from five to nine years after ward, eight patients from three to four and nine-tenths years afterward and seven patients from one to two and nine-tenths years afterward. For only fifteen of the group was the information available for a period of less than one year. Of these fifteen, five were unreported after the first episode of bleeding and five died within the first year.

Reexamination included not only a full history and physical examination but complete studies of the blood, including a red cell count, determinations of the hemoglobin and hematocrit content, bleeding time, clot retraction time and coagulation time, a platelet count, a leukocyte count and examination of the blood smear, as well as a tourniquet test and in some cases the intracutaneous test with snake venom.

SEX, RACE, AGE AND FAMILY HISTORY

There were twenty-seven male patients and thirty-five female. This sex incidence in our cases is somewhat unusual, it being generally believed that purpura haemorrhagica occurs much more frequently in females than in males, perhaps in a ratio of 2:1. Study of other reports leads us to believe that 4:3 is more accurate.

Only four of our patients were Negroes, although the ratio of Negroes to white persons admitted to the Johns Hopkins Hospital is 3:7.

It is of interest that in forty of our cases (64.5 per cent) symptoms of purpura appeared before the age of 12 and that, in fifteen more, symptoms developed between the ages of 12 and 24, making a total of 88.7 per cent (fig. 1). In six cases symptoms developed in patients from 46 to 54 years of age.

The incidence of purpura haemorrhagica in early life is well recognized. In figure 2, data compiled from the records published by Eliason and Ferguson⁴ and by Brown and Elliott,⁵ as well as from our own cases have been used to show the age incidence in 271 cases. In 62.8 per cent of these cases purpura haemorrhagica appeared before the age of 21.

It may also be pointed out that thirteen of our patients (six males and seven females) gave a definite history of ready bruising and frequent epistaxis or other forms of bleeding in other members of the family, and in two instances death had occurred from this cause. One family history which is particularly impressive is shown in figure 3. The familial or hereditary form of purpura which is best known is characterized by a normal platelet count in spite of prolonged bleeding time.⁸ Hess,⁹ however, noted the familial occurrence

Because of lack of space this article is abbreviated in THE JOURNAL. The complete article appears in the authors' reprints.

of thrombocytopenic purpura, and Witts¹⁰ also has observed such cases

The onset of purpura haemorrhagica in early life, the predominance of this disorder in the white race and the frequency of a relevant family history are features which suggest the possibility of a constitutional predisposition to the disease

THE COURSE OF THROMBOCYTOPENIC PURPURA

The course of the disease in each of the patients is indicated in figures 4, 5 and 6. The division of medically treated patients into those in whom only one episode of bleeding occurred (fig 4) and those in whom second attacks of hemorrhage developed (fig 5) is purely artificial, for some of the patients could not be followed and their subsequent history is unknown, while other patients, observed more recently may yet show further symptoms. Nevertheless the division is useful for purposes of description. Patients on whom splenectomy was performed are shown in figure 6.

The cases grouped in figure 4 differed considerably in severity. In about a third, hemorrhage was confined to the skin; in another third there was bleeding from the nasal and oral mucous membranes in addition, while in another third bleeding occurred also from the gastrointestinal or the genito-urinary tract. In more than half of the cases (fourteen) the platelet counts were lower than 50,000 per cubic millimeter. Eleven patients received transfusions, one receiving as many as six.

Two of these twenty-five patients died during the first episode of purpura. Hyperthyroidism was a complication in one (case 53), a woman of 51. In spite of repeated transfusions, the patient died of subdural hemorrhage and bleeding into the right auricle, after an illness of fourteen days. The second case (54) was complicated by pregnancy (five months).

The episodes of purpura in the twenty-three cases in which recovery occurred lasted from seven to forty-five days, averaging nineteen and seven-tenths days, except for two episodes of 119 and 120 days, respectively.

In four cases (6, 7, 8, 9) cessation of bleeding was associated with a well marked increase in the number of platelets, in two others (11, 12) a rise in the platelet count followed a few days after the cessation of bleeding, the count in one instance reaching 600,000 per cubic millimeter. In many cases, however, the increase in the platelet count was gradual and distinctly slower than the symptomatic improvement.

In eight cases ready bruising persisted after recovery from acute symptoms. Four of the patients (34, 35, 36, 37) still showed slight thrombocytopenia and positive reactions to the tourniquet test and the intracutaneous test with snake venom two, two, four and thirteen years, respectively, after the original episode of purpura. In two cases (8, 10) ready bruising had persisted for five and eleven years, respectively, after recovery from the attack of purpura, but when these patients were examined ten and thirteen years, respectively, after the attack they were symptom free and their blood was quite normal. In ten cases followed from one

to eighteen years after the attack of purpura, no physical or hematologic signs of purpura were found at the end of the period of observation.

Examination of the individual case records failed to reveal any correlation between the severity or duration of the episode of hemorrhage and the subsequent course.

In eighteen cases (fig 5) more than one episode of bleeding occurred. These episodes in some cases were as many as four in number and appeared at intervals ranging from one month to as long as fourteen or

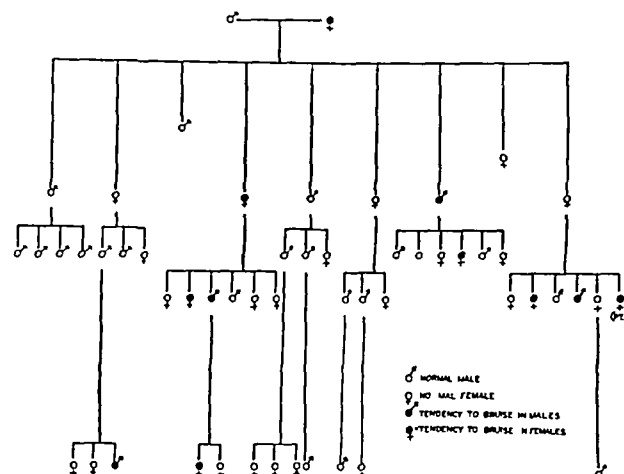

Fig 3—Family tree of a patient suffering from purpura haemorrhagica showing members in the family who tend to bruise very easily.

twenty-six years after the first episode. One patient (case 46) died of an intracranial hemorrhage eight and one-half years after the first episode of bleeding, after a symptom-free interval of six years. Another (case 28) was admitted fourteen years after a relatively mild attack of purpura. At this time the patient was pregnant and the purpura was severe. She died as the result of a diaphragmatic hemorrhage. In at least the preceding five years she had been completely free from symptoms, and two normal deliveries had occurred three and four years before the fatal attack of purpura.

Judging by the first episodes of bleeding, it would be difficult to distinguish the recurrent cases of figure 5 from the nonrecurrent cases of figure 4.

Symptomatic improvement following the first episode of bleeding was known not to have been accompanied by a "platelet crisis" in three cases (21, 23, 24). Nevertheless, in these and in six more cases recovery, as judged by symptoms, seemed to be complete. In the remainder of the cases grouped in figure 5, symptoms or signs of various degrees persisted. Subsequent episodes varied greatly in duration and severity and seemed to have no relation to earlier episodes or, for that matter, to the interval history.

Of the group of eighteen patients with recurrent disease, six have remained well and shown no abnormalities in the blood from three to eleven years after the last episode of bleeding. Six other patients (26, 38, 39, 40, 41, 42), however, have continued to show symptoms and signs in variable degree for many years and may be considered to have "chronic" purpura.

Death occurred in four of these eighteen patients. It is of interest that in three (cases 27, 28, 46) the fatal episode appeared after an interval of several years' freedom from symptoms. The fourth patient (case 45) died of cerebral hemorrhage following improvement of almost three months' duration.

Fig 2—Age incidence of purpura haemorrhagica (271 cases)

to the tourniquet test and the intracutaneous test with snake venom two, two, four and thirteen years, respectively, after the original episode of purpura. In two cases (8, 10) ready bruising had persisted for five and eleven years, respectively, after recovery from the attack of purpura, but when these patients were examined ten and thirteen years, respectively, after the attack they were symptom free and their blood was quite normal. In ten cases followed from one

¹⁰ Witts L. J. The Hereditary Hemorrhagic Diathesis. *Guy's Hosp Rep* 82: 463 (Oct) 1912.

The cases in which splenectomy was carried out are shown in figure 6. In eight patients the operation was performed during the first episode of purpura. All had severe bleeding from the nose and mouth and four from the alimentary or genito-urinary tract as well. Thrombocytopenia was marked. All had received blood transfusions, two having been given five and

Fig. 4—Course of purpura haemorrhagica in twenty five patients in whom only one episode occurred. All were treated medically. The hollow blocks indicate mild episodes, the blocks with diagonal lines moderate episodes and the solid blocks severe episodes. The duration of the episode is shown by the width of the block. The time of observation is indicated horizontally. The dotted lines show that there have been no symptoms. Continuation of symptoms is indicated by the continuous lines, the thickness of which roughly parallels their severity.

six, respectively. In three cases (58, 59, 60) the bleeding had been of relatively short duration, from seven to eighteen days, before splenectomy was resorted to, but in two the bleeding was very severe. Operation was not performed on the remaining six patients until bleeding had continued for several weeks (from thirty to ninety-seven days, average fifty-eight days).

Fig. 5—Course of purpura haemorrhagica in eighteen patients in whom more than one episode occurred. All were treated medically.

In eleven cases operation was performed during later episodes of bleeding. The first episode had usually not been as severe as in the aforementioned eight cases, although in two (29 and 44) the first episodes had been very severe. Relapse occurred at various intervals after the initial episode, in one case (29), nine years afterward. On this occasion the patient's condition was decidedly grave, cerebral hemorrhage having occurred. Splenectomy was performed and complete recovery followed.

Subsequent episodes which led to operation were varied in duration (from two to 430 days). In all instances bleeding was severe. Operation was performed in the face of symptoms of intracranial hemorrhage in two cases, the one previously mentioned and one (case 31) in which the residue of the hemorrhage caused jacksonian epilepsy.

Three patients died after operation, two (33 and 62) of shock and the third (51) of multiple abscesses of the lungs twenty-four days after operation. Prompt improvement followed splenectomy in all but one of the remaining cases, and even in that one (50) there was an appreciable decrease in bleeding. Improvement was associated with a well marked increase in the

platelet count in nine cases (55, 57, 58, 60, 30, 32, 44, 48, 49), but in four (56, 59, 61, 43) the platelets increased in number slowly.

The course of the disease in our sixty-two cases is summarized in figures 7, 8 and 9.

COMMENT

It is evident that the first manifestations of purpura haemorrhagica may be mild or fulminating. The initial symptoms may disappear, never to recur, or they may progress without interruption and cause grave anxiety. Relapses or recurrences may take place at unpredictable times and may be more serious or less acute than the original episodes. So variable is the course of this disease that it is impossible to predict with any degree of assurance what the subsequent progress of a given patient is likely to be.

The majority of our patients were treated by medical measures. Many received blood transfusions. Three patients were subjected to ultraviolet irradiation and four to roentgen irradiation over the spleen. In three of the latter splenectomy was ultimately performed.

Fifteen patients received no treatment other than the administration of iron when it was needed for the anemia. In seven recent cases snake venom therapy⁷ was employed.

In table 1 all these methods are grouped under the head of medical treatment and the results of such treatment are compared with those following splenectomy.

Recurrence, Relapses and Chronicity—In the patients treated medically, although immediate recovery or improvement was common after the first episode of bleeding, continuation of symptoms or signs in mild degree relapse or recurrence was not unusual. Continuation of the immediate recovery occurred in only 29.8 per cent (fourteen) of the forty-seven patients treated medically, regarding whom such information is available. The majority of the relapses (72 per cent) appeared within four years of the preceding episode, but, as previously mentioned, we have observed serious relapses after uneventful intervals of eight and one-half and even fourteen years. Only eight of the fourteen patients who showed continuous recovery have been followed for more than four years.

A curious feature regarding relapse was its frequency in females and relative rarity in males. Although only 56.5 per cent of our patients were

splenectomy. This fact is probably the more significant because some of the patients who were operated on were more seriously ill than those treated medically. Particularly impressive are the figures for continued recovery following splenectomy during the first episode of bleeding, in contrast to the frequency with which

Fig 6—Course of purpura haemorrhagica in nineteen cases in which splenectomy was carried out. Splenectomy is indicated by the letter S.

females, relapses occurred in twenty-five females and nine males, whereas complete recovery from the first attack occurred in four females and fourteen males. Nevertheless, in only eight instances were the recurrences associated with bleeding from the genital tract.

Relation of Rapid Increases in the Number of Platelets to Continued Recovery—In table 2 the available data concerning rapid increases in the number of platelets during recovery after medical care and after splenectomy are summarized. It appears that relapse was less common in cases in which a rapid increase in the platelets was associated with recovery than in those in which an increase was not observed. The point probably deserves no emphasis, however, for the total number of observations is small and such exceptions occurred as to cast doubt on the significance of platelet "crises."

Effects of Splenectomy—Because our own series of splenectomies is small in comparison with the number of patients treated medically, comparison is made in table 1 with the results of splenectomy in cases reported from three other clinics¹¹ as well.

In every respect except mortality following operation during the first episode of purpura the data favor

signs or symptoms of various degrees persisted when the patients were not operated on. The favorable figures for continued recovery following operation must, however, be weighted for the fact that 20.8 per cent of the patients died after operation, thus removing cases with a possibly less favorable course.

As has often been stated, operation during an acute episode is extremely dangerous. It should also be pointed out that after operation the condition of the patient may be critical even though death does not

Fig 7—Immediate (inner circle) and late (outer circle) results in all sixty-two cases of purpura haemorrhagica. Further details are given in figures 8 and 9. In these charts subsequent episodes refers to a return of symptoms and signs after apparently complete recovery; the cases which remained chronic are those in which symptoms and signs continued although no marked exacerbations developed. When exacerbations occurred in chronic cases they are referred to as relapses.

occur. One of Giffin's¹¹ patients had a stormy convalescence and required eleven transfusions. Three other patients in his series had a considerable amount of bleeding from the operative wound, although none of them required transfusion. Shock, acidosis, severe

11 Giffin, McLean, Kreidel and Caffey, Brown and Elliott.

epistaxis and various infections developed postoperatively in Brown and Elliott's⁵ patients. One of our patients had severe nosebleed nineteen days after operation.

Somewhat less impressive, although still definitely favoring splenectomy, are the results of operation during or after second or later episodes of purpura. Continued recovery was more common than in the

splenectomy the platelet count was not below the "critical level." Furthermore, in patients with thrombocytopenia, symptoms were common, whereas when the platelet count was not significantly reduced, symptoms were unusual.

Association of Purpura and Pregnancy—Purpura was associated with pregnancy in four of our cases. One fatal relapse occurred during pregnancy, as already mentioned (case 28). This patient had had two preceding normal deliveries. Another patient (case 25) had had three episodes of purpura, at the ages of 22, 24 and 26, and had also had two normal deliveries at the ages of 21 and 23. She appeared again at the age of 30, while pregnant.

In two instances purpura appeared for the first time during pregnancy.

In one patient (47), a primipara, cutaneous purpura first appeared during the seventh month.

In the second case (54) the disease was more severe and the patient died in the fifth month of pregnancy of cerebral hemorrhage. Pregnancy nine months before had been uneventful.

CONCLUSIONS

The dramatic subsidence of bleeding which often follows splenectomy has led many writers to advocate this operation in all cases of purpura haemorrhagica. Examination of the most enthusiastic case reports reveals the fact that such opinions are usually based on a limited experience. The data here presented are offered with the object of indicating the course of purpura haemorrhagica in patients treated by medical measures and in order that they may serve as a basis for comparison in evaluating other forms of treatment. It is evident that the course of the disease is varied so that all forms, from a simple, mild episode of bleeding

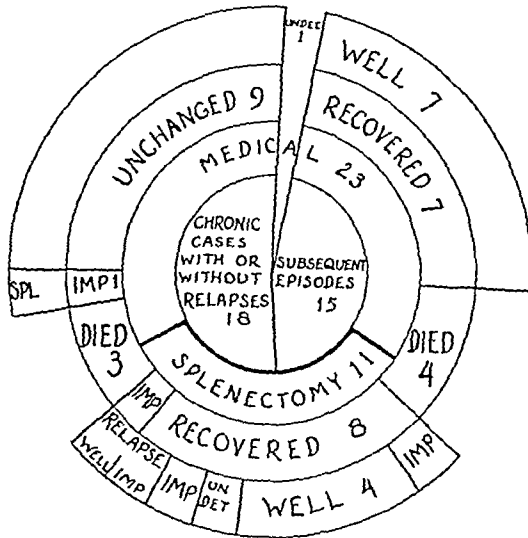

Fig. 8—The later course of the thirty four patients in whom symptoms again developed or who showed continuous symptoms after the first attack of purpura. Spl indicates splenectomy, medical implies nonsurgical treatment, imp improved, undet undetermined course.

patients treated medically, and continuation of symptoms or signs was less frequent. In this group even the figures on mortality tend to favor splenectomy. Judging by the data presented in table 1, it would appear that, if but one episode of bleeding has occurred, the chances for continued recovery are less than one out of three for patients treated medically and almost three out of four if operation has been performed. Against this favorable outlook must be weighed the dangers of operation. When several episodes have occurred the chances for continued recovery are again one out of three for patients treated medically and are somewhat better than even if splenectomy has been performed.

It might be added that serious complications are not always prevented by splenectomy. None have so far ensued after operation in our cases, but one of Giffin's⁶ patients died five years after splenectomy as the result of vaginal bleeding at puberty. Again, Whipple² cited three instances of intracranial hemorrhage following splenectomy, and McLean and his co-workers⁵ and Brown and Elliott⁵ each recorded one such case. It has been suggested that relapses following splenectomy are due to the presence of accessory spleens.¹²

The Platelet Count Following Splenectomy—It is often stated that hemorrhage does not recur after splenectomy even though, after an early marked increase, the platelet count again falls to "critical" levels.

Our observations agree with those of Anschutz¹³ in his study of fifty cases. In the majority of cases, after

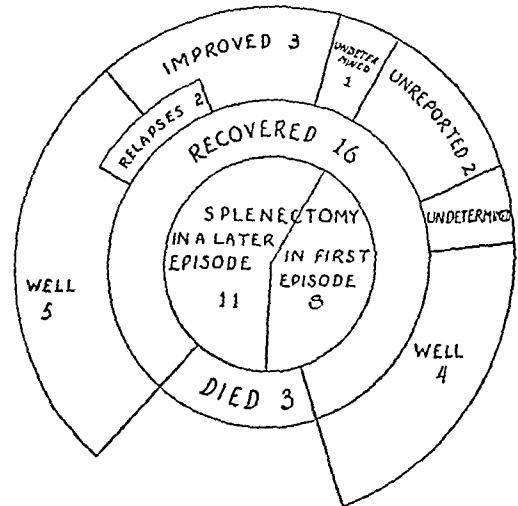

Fig. 9—Results following splenectomy in all nineteen patients treated. These cases are included in figure 7 and eleven are shown again in figure 8.

to a long continuous progression or a sudden recurrence of the fulminating disorder many years after the first episode, may occur.

In our opinion, there is no adequate basis for considering that by splenectomy the fundamental cause of purpura haemorrhagica is removed. In view of the available clinical and experimental¹⁴ studies and the

observed effects of splenectomy on this disease, it seems more plausible to consider that by splenectomy the cause of the disease is not attacked but an important site for the destruction of platelets is removed. Splenectomy is in this interpretation, the most radical of the methods for the symptomatic treatment of purpura haemorrhagica. If this is admitted, the indications for operation can be stated in relatively simple terms.

INDICATIONS FOR SPLENECTOMY

1 If the bleeding is severe and other more conservative measures have not been followed by remission, operation should be considered. In cases of this kind, patience is an important qualification for the attending

TABLE 3—Results of Reexamination of Patients Following Splenectomy

Case No.	Time After Splenectomy	Clinical Condition	Platelet Count per C. Mm.	Bleed. Ing. Time Min.	Clot Retraction	Tourniquet Test	Snake Venom Intracutaneous Test

48	7 years	Excellent	230 000	2¼	Good	Neg	
56	7 years	Excellent	234 000	2¼	Good	Neg	Neg

physician because (1) remission from an acute episode is the rule rather than the exception and (2) splenectomy is dangerous in cases associated with severe hemorrhage.

The decision as to the correct time for operation is a difficult one and the surgeon as well as the physician should have an opportunity to observe the patient early. Obviously one should not wait in deciding on splenectomy until the patient is a poor surgical risk. When adequate blood for transfusions is available, operation may perhaps be delayed longer than when it is scarce. It must be borne in mind that blood for transfusions may be required during and after the operation as well as before it.

2 Recurrences are more common in females than in males. Other factors being equal, operation should be considered more readily for girls and young women than for males.

3 If growth and development or the economic or social status of the patient is seriously impaired by recurrences of bleeding, even if the hemorrhage is only relatively mild, operation may then be considered advisable.

It should be remembered, first, that there is a genuine operative risk in splenectomy—danger of hemorrhage, shock, infection and postoperative pneumonia—and, second, that this risk is much lower during quiescent periods.

Little need be said concerning other measures used in the treatment of purpura haemorrhagica. We consider transfusion the most important. Our experience with snake venom therapy has been limited to seven

cases. While this experience has been favorable, we are not prepared to comment on this form of treatment at present. Irradiation of the spleen has recently been advocated again¹⁶ and seems to be worthy of trial. A few cases have been reported as favorably influenced by the administration of cevitic acid,¹⁷ but in other cases this treatment has failed.¹⁸ Many writers have stressed the importance of the removal of foci of infection.¹⁹ All these measures may well be tried. In cases in which relapse has followed splenectomy, it seems advisable to use these methods rather than to explore for accessory spleens.

SUMMARY

Sixty-two cases of purpura haemorrhagica were observed 64.5 per cent for longer than three years after the initial symptoms. Splenectomy was performed in nineteen of these cases.

The onset of the disease was found to be predominantly in childhood or adolescence. The sex incidence was almost equal. Negro patients in our series were rare. A family history of bleeding was noted in thirteen instances.

The course of purpura haemorrhagica as illustrated by these cases is extremely variable.

With medical care, recovery from an acute episode is the rule rather than the exception. Recurrences, however, are common. They occurred much more often in females than in males. A fatal relapse occurred in one patient fourteen years after the initial episode.

In our opinion, there is no adequate evidence for considering splenectomy as specific treatment for purpura haemorrhagica. It is the most radical of the methods for the symptomatic treatment of this disorder. There is an operative risk, and recurrences may follow operation. Nevertheless, splenectomy is decidedly the most effective of the therapeutic methods hitherto proposed.

ABSTRACT OF DISCUSSION

DR ALLEN O. WHIPPLE, New York. Purpura haemorrhagica is a middle ground disease. It is our feeling at the Presbyterian Hospital and at the College of Physicians and Surgeons that these diseases of the spleen should be studied by the combined group of physicians and surgeons and roentgenologists because it is only by the combined study that we can really arrive at fair estimate and the final evaluation of the results of treatment. This is well brought out by the authors in their discussion of this therapy. In the twenty-one years since the first spleen for purpura haemorrhagica was removed in Prague there has been no other paper as comprehensive in the follow-up period and in the careful analysis as this paper. In estimating our results at the Vanderbilt Clinic and the College of Physicians and Surgeons, we have felt that an accurate diagnosis was the most important primary consideration. To get as accurate a diagnosis as possible, we feel that the blood studies are exceedingly important and should be done by a group of expertly trained hematologists. The next important factor is the follow up of these cases, which should be done by both physicians and surgeons. We have a smaller

series of cases than that reported by the authors, and these were presented in a previous communication by Drs Brown and Elliott of the Spleen Clinic. In eleven of our patients, splenectomy has been done. They have been followed for an average period of five and one-half years. Five of them have been followed over six years, the longest follow up being eleven years and the shortest one year. The eleven nonsurgical cases are presented as a control group. They have been followed for an average period of four years, the longest follow up being eleven years and the shortest nine months. We have divided these into the completely arrested and the markedly improved. In the surgical group there were five and in the nonsurgical group three. One case was marked as improved in the surgical group and two in the nonsurgical group. There were no patients showing improvement in the surgical group, but five of the nonsurgical group continued to show their symptoms as they had previously, and they had been advised to have an operation but had refused.

DR GEORGE R MINOT, Boston. I am glad that Dr Wintrobe and his associates pointed out what seems to me frequently is little appreciated, namely, that the course of the disease is varied, it is one of remission and exacerbation. Do the cases of very short duration, in which frequently recovery occurs spontaneously within two weeks, represent the same disease as cases that may last a lifetime? We don't know. Certain drugs, such as sedormid and quinine, and occasionally food allergy may induce thrombopenia and may tend to create an intermittent type of disease. Such cases, of course are not suitable for splenectomy because the proper treatment is to remove the offending substance. One must distinguish conditions in which thrombopenia is a symptom. Purpura haemorrhagica may be the presenting symptomatology for as long as two months in cases of cancer widespread throughout the body, and occasionally the same may occur in cases of liver disease. Refractory anemias, discussed in the Section on Practice of Medicine by Dr Rhoads, are conditions to rule out. Leukopenia is characteristic. Beware of subjecting patients with leukopenia to splenectomy for purpura haemorrhagica, except in a rare instance. I have had occasion to see two cases which were proved by biopsy to be myelosclerosis, in which "idiopathic" purpura haemorrhagica appeared to be the correct diagnosis for over three years. In one, for three and one-half years there was no significant degree of anemia. In that case splenectomy was done when anemia began to increase. The patient is now living three and one-half years after splenectomy but continues to live by multiple transfusions with a red cell level of about two million. Relapse of purpura haemorrhagica is certainly commoner in females than in males. It is possible that this is because there are rhythmic fluctuations of the blood platelets in the menstrual cycle, they frequently fall just before menstruation begins and rise abruptly soon after the onset of the menses. Cases of intermittent purpura haemorrhagica associated with the menses occur. It was reported in *Naturwissenschaften* 24 314, 1936 that the injection in dogs of large amounts of progynon-B can induce drops of the blood platelets without alteration of the red or white cells. These various facts lead one to speculate on the possible role of some hormone control of the blood platelet level. The authors mentioned cases that developed during pregnancy. I have seen the same phenomenon, but I have also seen chronic cases improve during pregnancy. Again one wonders what role if any, altered endocrine function plays in these circumstances.

DR EDWARD M HANRAHAN, Baltimore. I noted that Dr Whipple was also interested in a group of cases for which there is no satisfactory name. They really form a middle group. Some have been called chronic. If one might use such a term as "threshold of symptoms," one might say that this particular group has a low threshold. Then the question might be raised, as Dr Minot raised it, whether or not this group really presents the same disease. At any rate, it is this group, continuously smoldering, constantly showing symptoms in greater or lesser degree, that challenges accurate diagnosis and renders judgment difficult as regards treatment. I notice that

the results of the authors correspond closely to ours. We have not had a late death after operation, although deaths are plentiful in the literature. The diagnosis of the disease is, of course, by exclusion, by the elimination of every other source of trouble that could give rise to a symptomatic purpura. We do not know the cause of the disease. We have had some success with the use of snake venom as a form of medical treatment, although the results have been of such duration that we are not prepared to comment more than that.

THE CLINICAL AND PATHOLOGIC IDENTITY OF PHEOCHROMOCYTOMA

REPORT OF A CASE

ARTHUR H WELLS, MD

AND
P G BOMAN, MD

DULUTH, MINN

During the last decade, the dramatic and diagnostic clinical manifestations of a new disease entity have been established beyond a doubt. Although isolated important characteristics of this malady were described earlier by several authors,¹ the first complete study of a classic case is that of Labbe, Tinel and Doumer in 1922. Since then, with ever increasing frequency, twenty-seven new case reports, all fundamentally clinical and pathologic duplicates, have appeared in the literature. The characteristic symptoms of thirteen² of these patients completely disappeared following the surgical removal of a benign tumor composed of the epinephrine-producing cells normally found in the

adrenal medulla. Necropsy or fetal surgery revealed the same neoplasm in the remainder of this group.⁴

Fifty-five additional reports of tumors of the same cells have been found. These may be divided into three groups of nearly equal size. In one no clinical history was given while in another the clinical manifestations noted were not at all suggestive of the disease. In the third group a fragmentary variety of suggestive symptoms was recorded. Critical reviews of the literature on the subject have been written by Wahl, Rabin, Eisenberg and Wallerstein, Lazarus and Eisenberg and Belt and Powell.

CLINICAL IDENTITY

Although pheochromocytomas have been found in children, the disease is primarily one of adults and it has an approximately equal sex distribution. Of possible importance among the factors precipitating the typical paroxysm is the accumulation of epinephrine in the tumor during rest of the patient with its release on physical activity, especially by flexion or torsion of the trunk. Psychic influences and extra-adrenal hormonal changes may play a role.

The occurrence of acute unpredictable attacks, lasting from thirty seconds to two or three hours, is the dominating feature. The patient suddenly complains of palpitation the severity of which may overshadow all other symptoms. There may be bradycardia or tachycardia and precordial pain or a sense of compression. The blood pressure taken at the onset of a paroxysm rises rapidly from normal levels to a systolic pressure of from 200 to 300 mm of mercury. In any given case the blood pressure may vary from day to day and from hour to hour, but it is generally normal between attacks. Later in the disease hypertension occasionally becomes permanent, and there may be superimposed paroxysms. During severe attacks there may be evidences of failure of the left ventricle with cyanosis, coughing, and frothy, blood tinged sputum. The respiratory rate may increase to 35 per minute and there is frequently a sensation of suffocation or choking. Cardiac hypertrophy, palpitation and dyspnea on

physical exertion and signs of congestive heart failure may develop late in the course of the disease.

A sudden transient spasm of arterioles accounts for many of the widespread manifestations. The skin suddenly becomes pale and cold at the onset of an attack to be followed in a few cases by flushing and profuse perspiration over the trunk. Numbness and tingling or pain and at times tremor are noted in the extremities. There may be a sensation of fullness in the head, cephalalgia, vertigo, low grade fever, muscae volitantes, blurring of vision, mydriasis and exophthalmos. Anxiety is often a prominent feature. Epigastric discomfort or pain, nausea and vomiting are common. As a result of relief from symptoms following emesis the patient frequently induces it early. Glycosuria has been noted and a two or three hour suppression of urine has been described.

Fig 1—Cut surface of neoplasm with a cap of normal adrenal tissue

Although these paroxysms may last only a few minutes some patients are left weak, tired and at times prostrated. The attacks tend to increase in severity and frequency, finally occurring several times a day and becoming completely incapacitating. Patients with the disease have been observed from a few months to twelve years. Cerebral hemorrhage, chronic congestive heart failure, acute left ventricular failure, Addison's disease, adrenal hemorrhage and probable hyper-epinephrinism have been important causes of death. With a few exceptions, even minor surgical procedures have been accompanied by serious and frequently fatal shock.⁶ The common and most likely clinical diagnostic errors have been essential hypertension, cardiac neurosis, hyperthyroidism, diabetes mellitus and renal tumor.

PATHOLOGIC IDENTITY

Neoplasms of chromaffin cells of the adrenal medulla and of the paraganglia located retroperitoneally along the vertebral column are the only proved tumors that have given rise to the typical clinical syndrome. Tumors of other sites, composed of the same or very similar cells e.g., the carotid body, may in time be found the basis of similar clinical manifestations.

Belt and Lowell¹, Rabin⁴.

Thus far there have been seventeen cases of malignant pheochromoblastoma reported, and only one of the patients suffered from the characteristic paroxysms. No crises have been noted in patients with neoplasms of the primitive neuroblastic cell precursors or the closely related ganglion cells of the adrenal medulla and sympathetic ganglions unless the tumor of Rogers⁸ is composed entirely of ganglion cells. It is more likely that this tumor contains a mixture of adrenal medullary cells similar to the case of Rosenthal and Willis.⁹ Pheochromocytomas have been equally distributed between the right and left adrenal glands. They rarely occur bilaterally and occasionally arise from paraganglions. The tumor has been too frequently associated with neurofibromatosis of the skin to be fortuitous.

Fig. 2—Section under low power

The chromaffin cells are distinguished from all other cells by their affinity for chromium salts. Apparently the epinephrine present in their cytoplasm reduces these salts to form an insoluble peroxide of chromium, which appears in the cytoplasm as fine brown granules. The epinephrine oxidizes spontaneously, so that tests (of which there are several) depending on its presence must be performed on fresh tissue. Several chemical analyses, including one extraction of the crystalline product,¹⁰ have demonstrated the presence of from 0.3 to 2 Gm. of epinephrine per hundred grams of neoplastic tissue. Although tumors weighing up to 1,000 Gm. have been described, the great majority are quite small,

many measuring from 5 to 10 cm. in diameter. They are encapsulated and rounded, and they frequently show some cystic degeneration of their otherwise solid homogenous, light brownish cut surface. The moderate cellularity, the relatively large polyhedral cells, with extreme anisocytosis and poikilocytosis in some areas and an atypical alveolar arrangement of cells in others are characteristic. The cytoplasm is abundant, vacuolated and finely granular, with characteristic inclusion bodies. The moderate sized nucleus may be multiple and contains a remarkably large nucleolus. The absence of fat, lipid and glycogen in the cytoplasm is an aid in differentiating the neoplasm from that of cortical origin. It is entirely possible that these tumors may be found to contain ganglion cells and neurocytes, as well as the chromaffin cells.

TREATMENT

Once the clinical diagnosis is established, the surgeon may find it difficult to decide which side of the abdomen to enter. The important aids in previous cases have been the palpation or x-ray demonstration of a mass or dislocated kidney, and in the production of symptoms by pressure on one side or the other. In any case, the anterior approach of Collier, Field and Durant³ is highly recommended. A 3 inch midline incision just above the umbilicus permits localization of the tumor on one or both sides. Then a transverse incision from the medial incision to the peritoneal gutter on the proper side makes possible early clamping of the blood supply of the neoplasm without much manipulation, thus avoiding the expression of epinephrine into the general circulation. Ether is a satisfactory anesthetic, while nitrous oxide and spinal anesthesia are contraindicated. In all cases the surgeon should be prepared to give blood transfusions during the operation because of the high frequency of severe shock in these patients. Post-operative hypo-epinephrism has not as yet been recognized. However, much remains to be learned about the cause of shock in these patients.

REPORT OF CASE

A woman, aged 30, a housewife and school teacher was admitted to St. Luke's Hospital in the service of Drs. D. F. Pennie and Robert Graham, through whose permission we are presenting this report, complaining chiefly of abdominal pain. Except for childhood diseases and bronchitis some years ago she had been in good health until about one year ago, when she began noticing sudden attacks of palpitation of only a few moments' duration. These were ushered in by severe pounding of her heart, 'like a sledge hammer,' and a 'peculiar feeling which ran over her body.' The attacks occurred frequently after periods of excitement, although they were often experienced at night. She had to give up watching basketball games and other exciting amusements because they left her worn out. A letter from home or unexpected company might precipitate an attack. There seemed to be no relationship to the menses or to physical work. She had noticed that she tired rather easily and was 'always ready for bed.' Otherwise she was in excellent health between attacks and led an active life. She might be sitting in a chair reading when a seizure began. She would anxiously ask her husband to look at her pale, cold hand and feel her pounding heart. At times spots appeared before her eyes. She became nauseated and by inducing vomiting she gained some relief.

Although the attacks lasted only from thirty seconds to two or three minutes, they left her so weak and tired that she had to go to bed for several hours. At first a severe headache developed after the episodes but this symptom became much milder during the last few months. The seizures occurred once or several times in a month and had been gradually increasing in frequency and severity.

Although it is not known that she was ever examined by a physician during an attack, blood pressures ranging from normal

to as high as 160 mm of mercury systolic and 110 mm diastolic were recorded. Physical examinations were otherwise entirely negative except for tortuous and spastic retinal arteries. Laboratory examinations, including complete blood counts, urinalysis, Wassermann test and basal metabolic rate, gave normal results. She was treated for essential hypertension.

The illness resulting in her hospitalization was incidental to the adrenal tumor and its manifestations but must be briefly related. The day before her death she left an evening theater performance early because of "feeling sick." She slept very little that night because of pain in the lower part of the abdomen and nausea, not associated with vomiting. The next morning she had a temperature of 100 F, tenderness and slight muscle rigidity in the right lower quadrant. She was more comfortable with her right leg flexed. Without further delay she was admitted to the hospital and rushed to the operating room.

The extraordinary succession of events which followed led to the tragically delayed probable diagnosis of pheochromocytoma before the necropsy was performed and before the clinical history of paroxysmal palpitation was obtained. She was given ethylene anesthesia and had not relaxed at the onset of the operation when her blood pressure began to rise and she became cyanotic. The anesthetic was discontinued and oxygen given in its place. The blood pressure rose to 180 systolic and 140 diastolic in ten minutes. Then it suddenly disappeared altogether. Many stimulants were given including several ampules of epinephrine and ephedrine. An acutely inflamed appendix was removed and artificial respiration begun. The patient was cyanotic and pulseless, breathed rapidly and shallowly, and had exophthalmos and dilated pupils. At times it was difficult to determine whether she was breathing at all. There were several generalized convulsions. At the end of an hour and a half of progressive loss of ground she was placed in a Drinker respirator, where in the course of ten minutes, her lips and cheeks became pink and she regained consciousness, moved her arms and legs and answered questions intelligently. The pupils remained dilated and there was a marked exophthalmos. An early attempt to let her breathe without the artificial help failed after a few moments. She was kept in the respirator for two hours and then removed to her room, where in the course of a few moments she became cyanotic and dyspneic and died.

At necropsy the patient was found to be remarkably well developed. Her previous exophthalmos had disappeared. A careful search failed to reveal significant gross or microscopic lesions other than a neoplasm of the right adrenal medulla (fig 1), moderate pulmonary congestion and edema, and a small abscess in the wall of the cecum near the stump of the recently removed appendix. The arterioles of the 325 Gm heart and of other organs were not abnormal.

The tumor had a complete thin fibrous capsule to which was attached a thin layer of atrophic cortical cells over one hemisphere. The latter were continuous with approximately one half of an otherwise normal suprarenal containing both cortical and medullary cells. The cut surface of the neoplasm was cystic and its color was tan with a faint tint of yellow. It turned dark brown after a few hours exposure to light. With portions of other organs from the same body as controls the adrenal tumor was assayed by the Folin Cannon and Denis¹¹ method. It contained 200 mg or 1 per cent epinephrine. The chromaffin reaction was positive. Histologically the neoplasm was moderately cellular, with a rather inconspicuous vascular stroma. The cells resembled those of the normal adrenal medulla except that they tended to be larger and occasionally had multiple nuclei (figs 2 and 3). The histologic diagnosis was confirmed by Dr E. T. Bell of the Department of Pathology of the University of Minnesota Medical School.

COMMENT

The necessity of developing more specific means of recognizing patients with the milder manifestations of the pheochromocytoma syndrome is obvious. The probable explanation of the crisis is a transient hyperepinephrinemia, resulting in seizures of sympathetic hypertonia. In lieu of a reliable method for determining blood epinephrine to prove this theory and to aid

in the diagnosis of the disease, Dr Irvine McQuarry¹² suggests the determination of blood potassium during attacks. It has been demonstrated by D'Silva,¹³ Schwarz,¹⁴ and Camp and Higgins¹⁵ that serum potassium rises as much as 86 per cent with the intravenous injection of epinephrine. Repeated studies should also be made of the blood sugar and the leukocyte count during attacks.

Since it may be difficult to examine the patient during an attack, some change in the patient's reaction to the injection of epinephrine may prove useful. Coller Field and Durant⁸ found their patient hyposensitive to epinephrine and suggest the use of the careful methods of Jensen¹⁶ in future cases. The complete disappearance of the typical syndrome during pregnancy in the

Fig 3—Section under high power

case of Kelly, Piper, Wilder and Walters⁹ and the transient relief with the onset of pregnancy in the case of Burgess, Waterman and Cutts⁴ suggest not only a possible means of diagnosis but also preoperative therapy through the use of gonadotropic substance or other endocrine products.

An extensive discussion of the relationship between excessive epinephrine secretion and the development of essential hypertension may be found in the literature. Whatever else may be said, it must be admitted that benign tumors of epinephrine-producing cells will cause spasms of the arterioles, ultimate chronic hypertension

and sclerotic changes in the arterioles and may terminate by one of the several modes of death common in essential hypertensive patients

SUMMARY

1 With the dissemination of the knowledge of the symptomatology resulting from benign tumors of epinephrine-producing cells during the last decade there has been a constant increase in the frequency of recognition and surgical cure of this new disease entity

2 Unpredictable paroxysms of hypertension associated with symptoms of palpitation, precordial sensations, epigastric discomfort, nausea, vomiting, pallor and coldness of extremities, glycosuria, cephalalgia and anxiety, in a patient apparently normal between attacks, are characteristic of the earlier stages. Later, chronic hypertension may develop as well as its usual sequelae

3 The characteristic surgical shock is less likely to occur during the excision of the tumor by selecting ether anesthesia, using an anterior operative approach, and by the use of blood transfusions

4 In the case reported, the typical clinical syndrome was not recognized by five physicians. The patient subsequently died of operative shock following the removal of an acutely inflamed appendix

TRIPLE PRIMARY CARCINOMA IN OTOLARYNGOLOGY

J C DROOKER M.D.

BOSTON

Triple primary carcinoma is a very rare entity. Warren and Gates¹ published statistics on 1,259 verified cases of multiple primary neoplasms which were taken from the records of approximately 115,000 postmortem examinations. In these 1,259 cases there were only thirty-seven instances in which there were more than two primary malignant tumors in one individual. All thirty-seven were triple carcinomas. This made an incidence of 2.9 per cent of primary triple neoplasms in their series of multiple primary tumors. On the basis of all statistics available both here and on the continent the frequency of multiple malignancy is 1.84 per cent of cancer cases. At the Mayo Clinic, where the incidence of malignancy is probably higher than in general hospitals, Hanlon² recently added forty-nine cases of double primary carcinoma, but in no one patient did he find a record of three primary neoplasms.

CLASSIFICATION

The criteria necessary for the diagnosis of multiple primary malignancy were first laid down by Billroth³ in 1860, seventy-seven years ago. He postulated that

- 1 Each tumor must have a different histologic appearance
- 2 Each tumor must arise in a different site
- 3 Each tumor must produce its own metastases

Meicaanton⁴ in order to rule out the possibility of recurrences added a fourth requirement, stating that there must be no reappearance of the tumors after removal.

From the Mosher Laboratory, Massachusetts Eye and Ear Infirmary. Read before the Section on Laryngology, Otology and Rhinology at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 11, 1937.

It is now the belief of many pathologists that these standards are too restrictive. For example, in criticism of the first statement in the tumors from two different organs the cells may be histologically the same and yet the tumors may be entirely independent of each other. In criticism of the third statement, it is known that there are malignant tumors which do not ordinarily have metastases, e. g., basal cell carcinoma and adenocarcinoma of the fundus of the uterus.

It is, however, justifiable to have a fairly rigid set of standards if reliable data are to be compiled, for it would otherwise be easy to include many instances of metastatic tumors in paired organs such as those of the ovary and breast and thus call them double primary malignant growths, or a far distant metastasis from a gastric carcinoma to the ovary might be called a primary tumor.

There are undoubtedly many instances in which any broad classification is inadequate. A case may present itself in which one tumor occurs and metastasizes, yet, when the patient comes under the observation of the clinician, the metastatic lesion may appear more advanced than the primary tumor. This occurs most frequently in tumors of the pharynx. It is seen in cases of transitional cell carcinoma of the pharynx, in which there may be large glands in the neck with but a very small primary tumor tucked away in the nasopharynx.

REVIEW OF RHINOLARYNGOLOGIC CASES OF TRIPLE CANCER

In studying the descriptions of all thirty-seven reported instances of triple primary carcinoma of different organs, I found three instances which are of interest to the otolaryngologist.

Fig. 1—Sketch of lesions in Nedopil's case.

The first case was that of Nedopil,⁵ an assistant in Billroth's clinic, who reported in 1877 a study which he called "Psoriasis of the Tongue and Buccal Mucosa and Its Relationship to Cancer." He reported fifteen cases in heavy smokers of cigars and cigars. This lesion was undoubtedly what would now be called leukoplakia.

One of the patients was a 52-year-old man who was a very heavy cigarette smoker. He had large white flecks on the buccal mucosa. There was no history of venereal infection. Two years later he had a carcinoma removed from the left lower lip followed by a plastic operation. Seven months later a mass the size of a hazelnut appeared on the mucosa of the upper lip which was excised a year later after unsuccessful therapy by the

⁵ Nedopil, N., Ueber die Psoriasis der Zungen und Mundschleimhaut und deren Verhältnisse zum Carcinom, *Arch. f. klin. Chir.* 20: 324-36, 1877.

chemical cautery, three years later the patient reentered the hospital because of a chronic ulceration 3 cm in diameter at the right angle of the mouth. This also was excised and one year later the patient had no symptoms of recurrence.

The second case was reported by Richter.⁶

A 62 year old man complained of dysphagia and vomiting for many months, the vomitus was sometimes blood streaked. The patient died fourteen days after his admission to the hospital and the autopsy demonstrated a large crater like ulceration at the base of the tongue extending down to the entrance of the larynx. The right half of the epiglottis also was eroded. On the right anterior wall of the esophagus behind the cricoid cartilage a white tumor mass measuring 2 by 4 cm penetrated the entire wall. In the esophagus below the tracheal bifurcation another tumor was found which was ulcerated and necrotic in the center. This led to a little cavity filled with foul smelling material situated between the esophagus and the right bronchus and communicating by a small opening with the right bronchus.

The wall of the esophagus between the upper and lower lesions was free from involvement.

The third case was reported by Hayward and Henderson.

The patient had three separate epitheliomas of the tongue. She was about 25 years of age and she had at first a large ulcer on the left side of the tongue adjacent to a sharp molar tooth. The ulcer developed into a deep cavern one half inch in diameter on the surface and 1 inch in depth from which she had severe arterial bleeding. Two days after the hemorrhage a deep ulcerated area developed on the opposite side of the tongue. About two weeks later another ulcer was noted at the tip of the tongue, which was believed to be malignant. Eventually the lesions from all these three points extended to a meeting point in the midline of the tongue. One

Fig 2—Sketch of lesions in Richter's case.

morning, eighteen months after the onset when the doctor was visiting the patient, she removed the anterior half of the tongue and presented it to him, the hemiglossectomy being caused by the coalescence of the lesions. About two months later the patient succumbed to cachexia and repeated hemorrhages.

REPORT OF CASE WITH SURVIVAL FROM TRIPLE PRIMARY CARCINOMA

The case presented fulfils all of Billroth's postulates.

The patient was a former Massachusetts Eye and Ear Infirmary attendant a widower, 62 years of age who had been a frequent visitor to the outpatient department of the Massachusetts General Hospital from 1923 to 1931 being treated there for hypertrophic arthritis and dental infection.

In September 1931 the patient complained of a small pimple on the right temporal region, which had become larger in a

period of nine months. Two areas were found on the right temporal region, one measuring 1 by 1 cm and the other measuring 0.5 by 0.5 cm. Both lesions disappeared with radium treatment administered in the dermatologic service. In May 1936 the patient noticed a recurrence of this lesion at the

Fig 3—Sketch of lesions in Hayward and Henderson's case.

same site as previously noted, which was growing rapidly (fig 4). The section shows all the typical histologic characteristics of a basal cell carcinoma.

In January 1932, a few months after the first basal cell carcinoma was treated, he complained of being unable "to clear his throat" and by indirect laryngoscopy an ulcerated mass was seen involving the left arytenoid. A biopsy proved it to be epidermoid carcinoma grade 4 (fig 5). The Hinton blood test and examination of the chest were both negative.

Fig 4—Basal cell carcinoma section under low power showing skin from the left temporal region. Note the deeply staining areas of basal cells just under the epithelial surface.

Feb 8 1932 a one stage total laryngectomy was done by Dr G H Poirier. A secondary closure of the neck wound was done twenty-four days later. The patient had a normal postoperative convalescence and worked as a parking stand attendant using an artificial larynx successfully.

Twenty-six months after the laryngectomy (April 7, 1934) the patient returned to the hospital complaining of pain about the tracheotomy opening. Microscopic examination of the granulations in the tracheal wound showed no evidence of tumor cells. However the patient had a large firm cervical node in the left side of the neck which was removed and found to be infiltrated

⁶ Richter, J. Zur Kasuistik der multiplen primären Karzinome. Wien klin Wchnschr 18 865 869 1905.

⁷ Hayward T E and Henderson R G. Multiple Epithelioma of the Tongue in a Woman Age 25 Years Resulting in Spontaneous Amputation of the Greater Part of the Organ. Lancet 2 22 23 1901.

with an epidermoid carcinoma grade 3 (fig 6). A block dissection of the neck was then done by Dr Poirier who removed all of the lymphatic, submaxillary and sublingual glands on the left side. This was followed by a course of high voltage roentgen therapy. It has now been approximately three and one-half years since the operation and there has been no evidence of recurrence in the throat or neck up to the present time.

Four years and three months after his original temporal basal cell cancer, Dec 28 1935, the patient presented himself again with an entirely different complaint, this time referable to his

Fig 5—Epidermoid carcinoma (grade 4) of the larynx section under high power showing very poor differentiation of epithelial cells. Note the many mitotic figures.

nose. He stated that he was having spontaneous intermittent attacks of epistaxis from his right naris for the previous seven weeks. This was associated with pain and right epiphora.

On examination a mass was seen obstructing the right naris in the region of the middle turbinate. A biopsy specimen from this area proved it to be an adenocarcinoma (fig 7). Surgical treatment was advised but the patient desired to temporize accepting roentgen therapy as a substitute. He was subjected to ten exposures of high voltage roentgen therapy with no improvement.

Fig 6—Epidermoid carcinoma section under low power showing a deeper staining tumor area within a left cervical gland.

The patient was admitted to the hospital nine months later Sept 23, 1936 because of headache, vomiting, severe pain in the right eye, increasing nasal obstruction and frequent attacks of epistaxis.

After the nose had been shrunk, a salmon colored mass was found to obstruct the whole right nostril and the septum pushed over to the left partially obstructing the left nostril.

The patient now consenting to surgical intervention was subjected to a modified right Moure operation performed by Dr LeRoy A Schall. A large soft mass was found filling the ethmoid labyrinth and was removed. The right nasal and

lacrimal bones were partially eroded. Four platinum needles containing 10 mg of radium were inserted in the operative defect for a period of 2,000 milligram hours. The microscopic examination of this tumor proved it to be adenocarcinoma (fig 8).

COMMENT

The case is presented as one in which it can be shown by microscopic proof that there occurred three separate and distinct primary carcinomas all situated above the thorax. The patient has survived all these three primary malignant tumors, one recurrence, and a grade 3 metastasis. He was seen May 20, 1937, and was found to be symptom free and showed no evidence of recurrence nine months since his last operation.

Nedopil's case of leukoplakia with subsequent carcinoma was proved at the postmortem examination. It cannot be dismissed without remarking that the development of three tumors in close lymphatic and anatomic relationship with one another may not simply be the extension of one primary neoplasm.

Richter's case also was diagnosed after death. Two tumors occurred at separate areas in the esophagus.

Fig 7—Adenocarcinoma section under low power showing the tumor from the right naris.

Here again it cannot be proved that the second tumor did not occur as a result of a metastasis or an extension through the lymphatics to a periesophageal lymphatic gland, which in turn repenetrated the esophagus and caused an esophageal-bronchial fistula.

Hayward and Henderson's case of multiple tumors of the tongue does not satisfy any of the precepts of Billroth. All three alleged tumors occurred in the same organ within a period of eighteen months and were clinically similar. The diagnosis of carcinoma was histologically proved in only one of the three tumors. Here again the primary tumor very likely extended to the two other areas by direct continuity or by implantation.

SUMMARY

The case from the Massachusetts Eye and Ear Infirmary shows three tumors in three separate regions, the lymphatic and venous drainage of these regions being in no way related to one another. The question of implantation by surgical manipulation is mentioned simply to exclude this possibility.

So far as I have been able to find, it is the only reported case in which surgical, roentgen and radium therapy of three separate and histologically different carcinomas occurring within the anatomic scope of the rhinolaryngologist has been survived.

CONCLUSIONS

1 Multiple primary neoplasms are rare, Warren and Gates quote it as occurring in 1.84 per cent of cancer cases

2 Triple primary neoplasms of miscellaneous organs comprise 2.9 per cent of all multiple cancer cases

3 Treatment of a patient afflicted with multiple primary neoplasms should be carried out as if they were single carcinomas

Fig 8—Adenocarcinoma section under high power showing tumor tissue removed from the right ethmoid. Note the many mitoses

4 In the case reported the requirements of Billroth concerning triple primary carcinoma are met. The patient has survived three primary carcinomas in areas of interest to the otolaryngologist

5 Three cases of triple primary malignancy have been reported which do not meet the requirements of Billroth's classification

243 Charles Street

ABSTRACT OF DISCUSSION

DR FRANK W. KONZELMANN, Philadelphia. The criteria that Dr Drooker has presented must be strictly observed in the diagnosis of multiple tumors. Any departure from such criteria is certain to lead to the inclusion of recurrent or metastatic single tumors in this rare and interesting group. Not so long ago at Temple University Hospital, there was a patient who had a tumor of the hard palate which proved on microscopic examination to be a squamous cell carcinoma. X-ray treatment was administered and after an interval all signs of tumor seemed to have disappeared. Months thereafter a second tumor appeared on the uvula. Histologically it was similar to the original lesion. Combined surgical and x-ray treatment removed the second neoplasm. Microscopic study of the mucous membrane removed over a wide area showed that the changes were widespread and that in all likelihood the second tumor was but a reappearance of the primary lesion. Microscopic study alone established the connection between the two. In another instance a patient presented a tumor mass in the groin. She gave a history of having had a lipoma removed from the neck, which was not studied histologically. A year previous to her admission to Temple University Hospital a second tumor, removed from the neck, was described microscopically as a neurinoma. The third neoplasm removed from the groin microscopically proved to be a melanotic melanoma. One cannot accept these as examples of three separate primary tumors without an opportunity of comparing the histologic structure. I believe this case demonstrates the wisdom of microscopic study of all neoplasms removed, regardless of their benign nature clinically. One can never know whether the original gross diagnosis of the first tumor, namely, lipoma, was correct. A case reported recently in THE JOURNAL in which there were a carcinoma of the left breast, a rhabdomyosarcoma of the left thigh and neurofibroma of the

skin of the neck cannot be questioned as an instance of multiple primary tumors. I agree with Dr Drooker that microscopic study is essential and that the criteria mentioned in his article must be strictly observed. It is equally important that each lesion should be treated as a separate neoplasm, for, as Dr Drooker has pointed out, some respond best to irradiation and some to surgical removal.

DR LOUIS H. CLERF, Philadelphia. Multiple primary neoplasms have not been common in my experience. I observed two cases at the Bronchoscopic Clinic, Jefferson Hospital in each of which there were two tumors which arose from different sites. One of these in a woman aged 53, was referred for investigation of a tumor of the left vocal cord. I found a squamous carcinoma of the larynx, grade 2. A satisfactory result was secured by thyrofixure. The patient was referred back about one year later because of the occurrence of an enlarged lymph node in the left supraclavicular space. It was assumed that this was a metastatic lesion from the larynx. There was no evidence of recurrence in the larynx itself, and no metastasis was observed in the regional lymph nodes. Further investigation revealed a growth in the left mammary gland with extensive axillary metastasis. The patient was referred to the late Dr E. J. Klopp, who made a diagnosis of carcinoma of the breast and considered the case inoperable. Radiation therapy was given and later the patient died from the carcinoma of the breast. In this case there was little doubt concerning the independence of the two tumors. Within the past two weeks another case of carcinoma of the larynx was referred for operation. This too presented a relatively early lesion, which was considered suitable for thyrofixure. A biopsy was done and a diagnosis of papillary squamous carcinoma was made. The patient gave a history of weight loss of about 30 pounds

Fig 9—Patient who survived three primary carcinomas, a recurrence and a metastasis (May 20, 1937)

(136 Kg.) and indigestion for over a year. X-ray and gastroscopic studies revealed a carcinoma of the stomach. Exploratory laparotomy was done and an adenocarcinoma with extensive metastasis was found involving the pyloric end of the stomach. Here again was a case of two independently located lesions, each of different histologic structure. At the Radiologic Clinic, Philadelphia General Hospital, I observed two interesting cases of multiple cancer. A man had a squamous carcinoma involving the skin of the nose and later a squamous carcinoma involving the floor of the mouth developed. It is hardly prob-

able that either of these could have been considered as a metastasis. The other case unfortunately was not completely studied from the standpoint of microscopic examination of tissue. Three lesions apparently independent of one another developed in a man within a period of ten years. In 1926 a prickle cell carcinoma of the left auricle was removed by amputation of this structure. In 1930 a lesion of the face developed which was believed to be a skin cancer but cleared up under x-ray treatment. Unfortunately, no biopsy was made on the face lesion. Its appearances were suggestive of carcinoma. In 1936 a lesion developed involving the right auricle. This proved to be squamous carcinoma.

DR HARRIS P MOSHER, Boston. In reviewing the pathologic reports at the Mosher Laboratory for the past seven years, I have not found any cases of multiple malignancy other than the one presented. It is likely that because of the limited study to a small portion of the body, multiple primary tumors are not seen more frequently. My belief is that a second or even a third primary malignant tumor occurring in one person is simply a coincidence. The involved unknown factors that are present in the etiology of cancer may manifest themselves in different organs. With our present limitations as to the knowledge of the genesis of multiple primary tumors, I think that they should be treated as in the case reported, as if the three cancers occurred in three separate persons. The case report brings up an interesting point in the treatment of cancer of the larynx. It is generally believed that a grade 4 epidermoid carcinoma of the larynx should not be treated surgically but preferably by x-rays. Metastatic glands developed on the left side of the neck two years after the removal of a grade 4 carcinoma of the larynx. Since their removal, this patient, apparently one with a carcinomatous constitution, has had a three year arrest from both grade 3 and grade 4 cancer of the neck.

VESICAL DYSFUNCTION FOLLOWING ABDOMINOPERINEAL RESECTION

FOR CARCINOMA OF THE RECTUM

MALCOLM R. HILL, M.D.

ROGER W. BARNES, M.D.

AND

CYRIL B. COURVILLE, M.D.

LOS ANGELES

As a result of experience with a number of cases of abdominoperineal resection for carcinoma of the rectum, it became apparent to one of us (M. R. H.) that vesical dysfunction occurred too often after operation to be considered as an incidental complication. Its frequency suggested that it would be given serious consideration in the literature. When this was found not to be the case, an earnest attempt to study the problem seemed to us to be very much worth while.

Since a complete investigation of the problem required the cooperation of the departments of proctology, urology and neurology, this paper is the result of studies conducted along several lines. It is our purpose to give a short survey of our own experiences as exemplified by typical cases, to review the experiences of contemporary surgeons and to investigate the possible cause of the urinary disturbances.

Our conclusions are based on an investigation of urinary symptoms in a series of twenty-two cases which have recently come under our observation and on a series of anatomic dissections of the nerve supply of the bladder. The value of this study is considerably

enhanced because contemporary surgeons have in response to a questionnaire recently sent them, reported to us the incidence and nature of vesical disturbances in their cases.

CASE 1—Rectal bleeding and progressive constipation in an adult male. Diagnosis of carcinoma of the rectum. One stage abdominoperineal resection one year later. Transitory urinary retention following operation.

D. F., a landlord aged 62, who complained of rectal bleeding and progressive constipation for eighteen months was referred by Dr. Roy Cummings, he was first examined April 22, 1936. An annular carcinoma of the rectum with moderate fixation in the pelvis was found one fingerlength above the anus. The condition had been diagnosed one year previously, but the patient had sought relief meanwhile in Christian science. A preoperative cystoscopic study revealed mild inflammation of the bladder neck with slight median bar formation. There was no edema of the bladder mucosa. A preoperative cystogram was normal.

A one stage combined abdominoperineal resection was done April 28. A rather large annular malignant growth was found well below the peritoneal reflection. In spite of difficult dissection due to a fairly long, narrow pelvis and to the patient's obesity, it was believed that the nerve supply of the bladder was not traumatized.

Urinary retention was noticed immediately after the operation and was controlled by a retention catheter. A cystogram made six days after the operation showed a marked dome shaped fundus with slightly more bulging on the right side. A cystogram made twelve days postoperatively showed the contour of the bladder to be more normal but a slight cone shaped deformity of the fundus was in evidence.

A cystometric study was done twenty-seven days after the operation, and it showed an atonic bladder with the first desire to void apparent after 450 cc of solution had been injected producing an intravesical pressure of 12 mm of mercury. The capacity of the bladder was 550 cc with an intravesical pressure of 42 mm. The patient had a varying amount of vesical dysfunction for several weeks after which time normal micturition was resumed.

This patient evidently sustained a minor and recoverable degree of trauma to the parasympathetic fibers to the bladder. This was shown by the atonicity of the bladder musculature, as demonstrated by cystograms and cystometric study. Furthermore, the injury was greater on one side than on the other, as indicated by the greater prominence of the dome of the bladder as shown in the cystogram. It is anticipated that normal vesical function will be completely restored in this case.

CASE 2—Symptoms suggestive of chronic appendicitis in a 42 year old woman. Abdominal exploration for acute intestinal obstruction. Carcinoma of the rectosigmoid associated with polyposis of the entire colon. Subsequent one stage abdominoperineal resection. Immediate urinary retention with rapid recovery but persistent atonicity of the bladder.

O. B., a housewife aged 42, referred by Dr. Glenn Curtis had for many months complained of symptoms suggesting chronic appendicitis. Because of an acute intestinal obstruction an abdominal exploration was done. An obstructive lesion was found in the sigmoid part of the colon. The large bowel was considerably distended. A palliative simple colostomy was done. The patient was seen in consultation on the eighth postoperative day. At this time a napkin ring type of adenocarcinoma was observed to involve the rectosigmoid junction and to be associated with polyposis of the entire colon. A combined abdominoperineal resection was done without difficulty eight weeks later. A normal preoperative cystogram showed considerable depression of the fundus due to pressure by the uterus.

Urinary retention persisted for five days after resection. It was controlled by interval catheterization. A small amount of residual urine persisted for several weeks. A cystogram made two weeks after the operation showed the uterine depre-

sion in the fundus of the bladder to be entirely absent. In its place a somewhat cone-shaped outline was observed and numerous cellulæ and small diverticula, more marked on the left side, were demonstrated. A cystogram made six weeks after operation showed the greatest diameter of the bladder to be transverse, assuming a normal contour. A certain amount of trabeculation was shown to have persisted on the left side.

A cystometric study four months after the operation disclosed a very atonic bladder, a desire to void at a volume of 250 cc and a pressure of 12 mm of mercury, a total capacity of 450 cc and no increase in intravesical pressure above 12 mm.

There was evidently a rather severe injury to the parasympathetic elements at the time of operation as shown by the marked change in the contour of the bladder. An interesting observation is the formation of cellulæ and diverticula within so short a period after operation (two weeks). Ordinarily these alterations occur only after months or even years of urinary retention due to paralysis or obstruction. Marked atonicity of the bladder still persists as shown by cystometric studies. While some difficulty in voiding and slow stream still persist after four months it is likely that normal function will ultimately be restored.

CASE 3—Colostomy followed by radiation therapy for presumed carcinoma of the rectum. Low grade adenocarcinoma disclosed by subsequent biopsy. Combined abdominoperineal resection. Growth adherent to vaginal wall. Immediate complete urinary retention with partial recovery in two months.

C C, a woman aged 40, was referred by Dr C O Bailey, a radiologist, who had given her radium therapy for carcinoma of the rectum. A colostomy had been performed in August 1936 by an osteopathic surgeon after a diagnosis of carcinoma of the rectum, with much hesitation and delay. Examination Feb 18, 1937, disclosed a long tubular stricture extending from midrectum well up into the pelvis. A biopsy disclosed an adenocarcinoma, grade 1. To rule out lymphopathia venereum a Frei test was done, the results were negative. A preoperative cystogram proved to be normal showing no uterine depression in the fundus.

A combined abdominoperineal resection was done April 2, 1937. The malfunctioning palliative artificial anus was removed and a colostomy was done, a permanent opening being placed in the midline at the level of the umbilicus. A malignant growth was present in the form of a tubular stricture extending from midrectum well up into the sigmoid loop above the peritoneal reflection. There was definite fixation to the posterior vaginal wall, which had to be resected.

Complete urinary retention occurred immediately after operation. It was controlled first by retention catheter and subsequently by interval catheterization. A cystogram made two weeks after operation showed a dome-shaped deformity on the left side of the bladder, the right side being quite flat and approximately normal in appearance. A cystogram made four weeks after operation showed the dome-shaped deformity to be less marked. At a cystoscopic examination four weeks after operation, 100 cc of residual urine was found. The bladder mucosa was inflamed. The tone of the bladder musculature was considerably decreased, suprapubic pressure being necessary to empty the bladder through the cystoscope.

A cystometric study made seven weeks after operation showed a fairly rapid early rise in intravesical pressure with a desire to void when the volume was 200 cc and the pressure 40 mm of mercury. The capacity of the bladder was 500 cc, with a pressure of 70 mm.

In this case the cystograms suggested a predominantly unilateral injury to the parasympathetic elements. This injury was not severe, but its effects have persisted for two months. The intravesical pressure, as determined by cystometric studies, was undoubtedly increased by the inflammation of the bladder mucosa. This was

shown by the rapid rise in intravesical pressure. Although the vesical symptoms have persisted for two months a definite degree of recovery has already taken place, and complete restoration is hoped for.

EXPERIENCES OF CONTEMPORARY SURGEONS

A questionnaire was sent out to approximately 170 contemporary proctologists and general surgeons and seventy-one responded. For various reasons twelve of these did not fill out answers to questions submitted. The remaining fifty-nine filled out the blank as requested.

As to types of urinary complications encountered thirty-seven reported complete early retention, twenty-five partial early retention, thirteen partial early incontinence and four complete early incontinence. One reported partial late retention (after six months). Late incontinence (after six months) was mentioned as being complete by four and partial by twelve. Four of those mentioning late incontinence stipulated that in the cases they had observed it was nocturnal.

Fig 1—Dome shaped deformity of bladder following resection of the rectum for carcinoma. A transurethral prostatic resection was done after the resection accounting for the subvesical outpocketing.

Only twelve surgeons reported cystoscopic study in their cases. The conditions observed included diffuse cystitis with trabeculations, cystitis, trigonitis, pyelitis, prolapse, stricture, obstruction by connective tissue of the posterior part of the urethra and prostatic hypertrophy. One surgeon and author of repute reported that cystoscopy gave negative results in cases of incontinence. An American of wide experience in this field of surgery reported that in the many cases in which cystoscopy had been performed conditions were observed quite characteristic of true neurogenic disease of the bladder of the type seen with *tabes dorsalis* and other lesions which interfere with the nerve supply of the bladder.

The estimated percentage of vesical dysfunction following rectal resection observed by the fifty-nine surgeons varied from zero to 100. Thirty-two reported 50 per cent and over. Twenty reported that two thirds or more of their patients had urinary disturbances after resection. Nineteen reported an incidence of under 25 per cent. Seven reported 100 per cent vesical dysfunction in their series of cases. Seven declined to state

what their estimate would be. Four reported that they had no urinary complications.

The estimated time in which distressing urinary symptoms persist varies from a few days to three months. Twenty-eight reported symptoms present for one month or less. Seventeen declined to give their estimate. Ten reported an average of over one month in which symptoms of vesical dysfunction were present.

Fig 2—Diverticula of the bladder wall after rectal resection

Nine reported that symptoms were present for less than one week. Mention was made of cases in which symptoms persisted from twelve to eighteen months or more. In one case of nocturnal incontinence a penile clamp was necessary to control leakage.

One surgeon expressed the opinion that more injuries to nerve structures result in vesical dysfunction than commonly believed and that some patients never fully recover. The cause of vesical disturbance in cases of rectal resection was given as injury to sympathetic nerves by thirty-seven observers, reflex action by twelve, cystitis or inflammation by seven, trauma by five, lack of support following surgery by four, shock by one, interference with ureters by one, pressure from packing by one and contraction and scarring by one. One surgeon said that the fact that the nerve center for both bladder and rectum are in the same level in the spinal cord accounts for the urinary symptoms.

The technic recommended to obviate occurrence of vesical dysfunction following resection largely consisted of drainage of the bladder by indwelling catheter or repeated catheterizations. Irrigations with solutions of boric acid, potassium permanganate, silver nitrate and sodium chloride were mentioned. Instillations of mild protein silver, solution of silver nitrate, mercurochrome and solution of boric acid were also used. Diuretics and antiseptics by mouth were advocated by some. Mandelic acid was specifically mentioned. Support of the base of bladder, forcing the fluids and resection of the prostatic bar were considered as preventive measures. A number of surgeons mentioned one important precaution, which, as we shall show, is of paramount importance, i. e., staying close to the rectal wall in the course of resection, thus avoiding the nerves and hypogastric plexuses. On the other hand, some surgeons stipulated that it is necessary to disregard entirely the

nervous structures in dissecting out the regional connective tissue and lymph glands in order to prevent regional metastasis and recurrence. Spinal anesthesia is recommended as a means of obviating nerve disturbance.

TYPES AND MECHANISM OF VESICAL DYSFUNCTION FOLLOWING RESECTION OF THE RECTUM

A very interesting phenomenon is observed in serial cystograms taken in cases of rectal resection for carcinoma. Preoperatively the contour of the bladder has been found to be normal while postoperatively the picture proves to be radically changed. The bladder is passively distended, owing to atony of its musculature. This is indicated by the necessity of suprapubic pressure to empty the bladder when the catheter is in place and by cystometric studies. The fundus of the bladder becomes dome shaped (fig 1) and may present an irregular outline due to the occurrence of numerous cellules or even diverticula (fig 2). It has been generally believed that it requires months or even years of urinary stasis, either obstructive or paralytic, to produce these outpocketings of the bladder wall. On the contrary, we find these irregularities within two weeks after resection of the rectum. In some instances one half of the bladder shows them while the other half presents a normal, or nearly normal, contour (fig 3). This unilateral involvement is indicative of greater injury to the nerves on this side than on the other.

The bladder is supplied with sympathetic fibers from the four lumbar sympathetic ganglions by way of the presacral nerves and with parasympathetic fibers from the second, third and fourth sacral nerves by way of the pelvic nerves. These fibers form by their union dense networks of nervous tissue the hypogastric

Fig 3—Unilateral paralysis of the bladder probably due to injury of the parasympathetic fibers in the hypogastric plexus on the affected side

plexuses, which lie one on each side of the rectum just where it passes through the pelvic floor. From these plexuses, the nerve fibers are projected anteriorly into the walls of the bladder. Each lateral half of the bladder is supplied by nerve fibers from the hypogastric plexus on its own side (fig 4).

The sympathetic fibers have for their function the closure of the internal sphincter and inhibition of muscular elements of the bladder wall. The parasympa

thetic fibers, on the other hand produce contraction of the bladder musculature and relaxation of the internal sphincter, reacting reciprocally with the sympathetic elements. The external sphincter, under voluntary control, is supplied by the pudic nerves.

The picture presented by cystograms the results of cystometric studies and the patient's symptoms suggests an injury to parasympathetic nerves as the cause of vesical dysfunction following radical resection of the rectum. The location of the sympathetic fibers, somewhat distant from the rectum as they pass over the sacral promontory, seems to exclude them from operative injury. The parasympathetic fibers are probably traumatized near the rectum as it leaves the pelvis. These relationships are clearly seen in dissections of the human pelvis.

The nature and extent of injury to the parasympathetic elements varies considerably, judging from the observations in our series of cases. The injury may be minor and transitory. Incomplete injury may also be fairly extensive. In either case there has probably been stretching of the nerves, with temporary loss of function. While dysfunction may be marked prompt and complete recovery from the resultant symptom may be expected. On the other hand, if any number of nerve fibers have actually been sectioned a more persistent or even a permanent urinary disorder may result. The degree of residual dysfunction is probably indicative of the degree of injury to nervous structures, other possible causes for the disorder having been excluded.

The location and stage of growth of the carcinoma also has much to do with the extent of urinary dysfunction, since the extent of necessary dissection is predicated by these factors. The primary growth may be anal, rectal or rectosigmoid. In any case the characteristics of the local lymphatic drainage demand adequate and often radical resection with increased danger to the nervous elements. Furthermore, the extent of the growth, the degree of fixation in the pelvis, the amount of secondary inflammation and the extent of involvement of the regional lymph glands all influence the extent of resection and the danger of trauma to local nerves. It is clearly evident that the close relationship of the nervous elements to the lower part of the rectum makes injury an easy matter during resection. Yet when the pelvic viscera and supporting structures are carefully separated along their line of cleavage from the anorectal canal, a minimum of vesical disturbance need be expected.

TREATMENT OF VESICAL COMPLICATIONS

Catheterization is usually necessary when retention occurs after resection of the rectum. A varying degree of cystitis almost invariably develops. This condition is usually worse in cases in which catheterization has been neglected. In most instances the treatment of choice is an indwelling urethral catheter and daily lavages of the bladder with warm boric acid solution. For women a 16 or 18 F wing tip catheter is commonly used, while for men a double-eyed Robinson soft rubber catheter of the same size is preferable. The catheter is removed at least once a week, left out for eight hours, then reinserted immediately after the patient voids, the amount of residual urine being determined in this way. If this amount is more than 100 cc, the catheter is once more fixed in place. If residual urine is still present after the patient is allowed to be up, it is preferable to catheterize two or three times daily. When

the urine is purulent, lavage of the bladder with 1 to 6,000 solution of potassium permanganate followed by instillation of 15 cc of 1 to 1,000 silver nitrate solution is continued until the residual urine is less than 25 cc. It has been found that if an indwelling catheter is not used or frequent catheterization is not carried out as described, severe cystitis and, at times infection of the upper part of the urinary tract will develop.

SUMMARY AND CONCLUSIONS

1 Retention of urine with distention of the bladder as shown on the cystogram is a fairly common complication of resection of the rectum for carcinoma. Cellules or small diverticula, ordinarily the result of long continued obstructive or paralytic distention, may appear within two weeks.

2 Urinary retention may be transitory, may be present for days, weeks or even months or, occasionally,

Fig. 4—Dissection showing relationship of the hypogastric plexus to the rectum.

may be permanent. The extent and duration of vesical dysfunction depends on the character and extent of damage to the nervous elements.

3 The consequent paralytic atony of the bladder may affect one or both sides, depending on whether the nerves on one or both sides are injured.

4 The character of the urinary disturbance indicates that the parasympathetic elements are exclusively or predominantly affected. This suggests that the pelvic nerves themselves or the parasympathetic elements in the hypogastric plexuses are the seat of injury.

5 Anatomic dissections make clear the intimate relationship between the pelvic nerves and hypogastric plexuses and the lower part of the rectum where it penetrates the pelvic floor.

6 Injuries to these nervous elements are more apt to take place when the growth involves the upper part of the rectum or the lower part of the sigmoid flexure and when there is widespread involvement of the regional lymph nodes, with fixation to other organs or tissues.

7 Treatment of retention by an indwelling catheter is indicated as long as there is more than 50 cc of retained urine. If cystitis develops, which is most apt to occur in patients not catheterized, it should be appropriately treated with lavage of the bladder with potassium permanganate solution (1:6,000) and instillation of silver nitrate solution (1:1,000, 15 cc.)

ABSTRACT OF DISCUSSION

DR DUDLEY A. SMITH, San Francisco. In my series of 163 abdominoperineal resections for cancer of the rectum, a large percentage possibly 90, have shown some vesical dysfunction following this operation. Fortunately, for the most part the dysfunction has been transient lasting from one week to four weeks, and of a mild degree. In three of these cases there was serious dysfunction. One man had two years of catheter life until his death from another cause. In one woman there was dysfunction for about six months, which cleared up entirely. A third patient a man on whom I operated five years ago, has from that time had nocturnal incontinence, for which condition it has been necessary to use a penile clamp. I wish to thank the authors for their very careful study of this condition. It is a condition which has not been studied sufficiently heretofore. I believe that as a result of their work it will be possible to avoid much of the vesical trouble that follows this operation. It is clear from their investigation that the length of time vesical dysfunction lasts and its severity depend on the amount of injury to the nerve fibers.

DR DESCUM C. MCKENNEY, Buffalo. In a small series I found that two thirds of the patients were males and all required interval or indwelling catheterization. Of the other third, females, 40 per cent were able to void and 60 per cent required catheterization. The average length of time catheterization was required was six days. Retention of urine occurs in pneumonia with pleurisy, severe colitis, anal fissure, perianal and perirectal abscesses, thrombosed and infected hemorrhoids, and many other conditions. It occurs after many operative procedures, especially abdominal, such as herniotomy, appendectomy or hysterectomy. It may follow a curettage or an abdominal incision. It is quite evident that there is no direct injury to the sympathetics and parasympathetics in these cases. It would be interesting to compare the amount of vesical dysfunction in these cases with a similar number of cases of abdominoperineal resections. When a patient has much postoperative pain, he refrains from straining to void for fear of increasing it. On the other hand, when there is practically no pain following an operation the same thing may occur. The discomfort of trying to void in the recumbent position adds to the difficulty. Watchful postoperative care is necessary to make sure that when a patient voids following operation there is left as suggested not more than 50 cc of residual urine. It is advisable to catheterize as soon as the patient is unable to void and the bladder distends as a distended bladder has little power to contract. Eight hour or indwelling catheterization is undoubtedly less dangerous than retention. When catheterization is necessary, the oral administration of methenamine and acid sodium phosphate seems to decrease the incidence of cystitis. Some urologists believe that there is also considerable virtue in the administration of two tablets of sulfanilamide after each meal. The passage of very little urine in the first twenty-four or forty-eight hours after operation may be due to diminished secretion the result of operative shock, and it is better not to catheterize then if one can be sure of one's ground, as every catheterization adds to the danger of infection.

DR EDWARD G. MARTIN, Detroit. After a posterior resection, a man with no prior bladder difficulty had persistent necessity for catheterization, this condition continued for more than a year. Indwelling catheters and various other methods for relief were tried. After a year he had a suprapubic drainage and suprapubic prostatectomy. His symptoms were very soon relieved, and for the past year he has continued well. The prostate must be excluded as a complication in retention.

THE ROENTGEN ASPECT OF SYMPATHETIC NEUROBLASTOMA

HOWARD P. DOUB, M.D.

DETROIT

While sympathetic neuroblastomas were first described by Maichand, in 1891, as being derived from neural structures, it was not until 1910 that they were established as a separate and distinct clinical entity by the histologic observations of Wright.¹ Since that time many cases have been reported and much information has accumulated regarding their clinical picture and prognosis.

They are neurogenic in origin and are sometimes referred to as neuroblastomas or sympathoblastomas. Two disease syndromes have been described. The first, described by Pepper,² emphasized the adrenal origin, with early metastases in the liver and the early age at which the tumor appears. The second type, which was described by Hutchinson,³ occurred somewhat later. There were metastatic lesions in the skull orbits and long bones. A moderate degree of anemia was present.

Later studies have shown not only that these two types overlap but that they are indistinguishable pathologically and roentgenologically. As the tumors arise from undifferentiated cells of the sympathetic nervous system, their origin is not confined to adrenal tissue. They may also arise in the sympathetic ganglions along the spine, especially in the cervical area.

These tumors are seen most commonly in children under the age of 4 years but may also occur in adults and are said to be more common in males. They are in all probability congenital.

The initial symptom in my three cases was pain referred to the spine and the legs. In most reported cases the common complaint was an abdominal mass although in some instances the metastatic lesions attract the first attention. Loss of weight is usually present, and there may be vomiting. The child when first seen is frequently pale, undernourished and irritable. An abdominal mass may be the most prominent observation, while in some cases swelling about the face or skull is noted. Proptosis of one or both eyes with discoloration of the lids is common. Liefelder⁴ stated that the ocular signs are caused by increased intracranial pressure and metastases to the orbit. Choked disk was present in all his cases. Enlarged glands occur early or late. Bone pain, from metastases, may be the predominating feature at this time.

The clinical course is usually characterized by a rapid decline followed by death in a few months. There may be manifestations of temporary improvement following radiotherapy, but relapse soon occurs, and the downward course is resumed. The local tumors frequently appear to respond to radiotherapy, but this has no apparent effect on the development of distant metastases.

From the Department of Roentgenology, Henry Ford Hospital, Read before the Section on Radiology at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 10, 1935.

The roentgenographic changes are among the most interesting observations in this disease. The most constant changes are those associated with bone metastases. The changes in the skull consist of widening of the sutures and increased digital markings indicative of increased intracranial pressure. In addition there is evidence of involvement of the bones of the skull manifested by minute foci of resorption, which produces a finely granular type of osteoporosis. The flat bones of the pelvis show a type of infiltration similar to that in the skull. This type of bone involvement appears to be the characteristic lesion in the flat bones.

In the long bones various types of lesions are seen. Elevation of the periosteum is frequently present and may be local or may extend along the entire length of the shaft. Areas of metastatic involvement with bone resorption are seen in any of the long bones. These changes are more apt to be in the ends of the diaphyses, adjacent to the epiphyseal lines. In my cases the resorption in the upper ends of the humeri was the greatest along the medial border of the metaphysis. In advanced cases these changes may extend also the full length of the shaft of the bone. In many instances the resorption is of uneven density, suggesting a diffuse infiltration rather than a massive destruction, such as is seen in certain cases of osteoclastic carcinoma. Askin and

responding to the palpable mass. In exceptional instances the primary tumor may be seen overlying the upper part of the chest, as in a case reported by Hartung and Rubert.⁶

The tumor mass when removed is usually seen to be an encapsulated solid tumor. Askin and Geschickter⁵ found that the kidney was usually compressed rather than invaded. The adrenal was sometimes entirely displaced by the tumor mass. They found that metastasis to the retroperitoneal lymph nodes was more common than metastasis to the bones or liver.

Histologically, these tumors are quite cellular and are composed of small cells with hyperchromatic nuclei and a narrow rim of cytoplasm. The formation of rosettes by the cells is said to be one of the characteristic microscopic observations, but Askin and Geschickter⁵ saw it in only one third of their seventeen cases. These rosettes are characterized by a circular arrangement of cells about bundles of fibrillae. The characteristic cell is similar to the primitive migrating cells of the sympathetic nervous system.

High voltage roentgen therapy was administered in two of my cases and radium packs in the third. In two of the cases there was marked regression of the local growths but owing to the extensive metastases the relief was only temporary. The tumors were moderately radiosensitive. The clinical course was rapidly downward, with only temporary remission after radiotherapy. The average length of life from the time of my first observation until death was four and one-third months.

REPORTS OF CASES

CASE 1—History—D. M., a white boy aged 2½ years, was admitted April 6, 1935, for pain in the back, left hip and thigh. The family history was irrelevant. The child had always been well up to the time of the present illness.

Four weeks previous to admission he fell from a tricycle, and this fall was followed by slight disability for a few days. He was then well until a few days before admission. Pain had been present in the back and the left leg for several days. He was quite irritable.

Examination—The child was well developed, well nourished and not acutely ill. The upper part of the respiratory tract was normal. The chest and the abdomen were normal. He walked with a left-sided limp and held the leg flexed and in external rotation. There was no limitation of motion of the left hip. The left knee kick was not obtained. The lower dorsal and lumbar portions of the spine were flexed and could not be straightened out. At this time x-ray examination of the spine revealed no evidence of pathologic changes in bones or joints.

After conservative treatment for several weeks with the child on a Bradford frame a palpable mass appeared in the left lumbar area. Lumbar punctures gave no additional information. At this time x-ray examination was made of the spine, pelvis and long bones. It disclosed evidence of a finely granular type of osteoporosis in the pelvis, femurs and ribs. The humeri

Fig 2 (case 1)—Granular type of osteoporosis with localized areas of more intense bone infiltration.

Fig 1 (case 1)—Granular type of osteoporosis in the pelvis and femur.

Geschickter⁵ described these metaphyseal lesions as wedge shaped. I have been impressed by the osteoporosis of an extreme grade involving the metaphyses in certain cases before actual dissolution of the bone structure takes place.

In cases in which there are large abdominal masses, a diffuse shadow may be seen on the affected side cor-

⁵ Askin J. A. and Geschickter C. F. Neuroblastoma of the Adrenal in Children. *J. Pediat.* 7: 157 (Aug.) 1935.

⁶ Hartung Adolph and Rubert S. R. Roentgen Aspects of Sympathetic Neuroblastoma. *Radiology* 24: 607 (May) 1935.

and the spine were normal. Extensive osteoporosis was present in the diaphyses of the femurs.

A blood count showed 3,700,000 red cells and 12,100 white cells. A spinal fluid culture was negative. The Wassermann reaction was negative. An exploratory laparotomy was carried out, and a retroperitoneal tumor about 4 by 2 inches (10 by 5 cm) was found overlying the spine. A piece was removed for microscopic study.

The pathologic diagnosis was sympathetic neuroblastoma with metastatic lymph nodes.

Röntgen Therapy—High voltage roentgen therapy was administered over the abdomen, pelvis, femurs and knees. The following factors were used: 190 kilovolts, 50 cm focal skin distance, 0.5 mm copper and 1 mm aluminum filtration. From 600 to 800 roentgens was applied in fractional doses. Afterward the child improved clinically, and the tumor in the abdomen regressed until it was scarcely palpable, but the use of the legs did not improve. After several months, enlarged glands appeared in both sides of the neck and in both groins. The appetite became poor, irritability increased, and he declined rapidly. Death occurred Sept. 11, 1935.

Postmortem Examination—There was a large mass of retroperitoneal nodes. These were adjacent and attached to the left adrenal. They extended from the lumbar region to the mediastinum. A few nodules were observed in the liver and in the root of the lung. Areas of tumor tissue were present in the lumbar vertebrae.

Sections of the tumor tissue showed it to be composed of irregularly shaped islands of cells separated by fibrillar stroma. The cell nuclei were round, ovoid or polyhedral and were hyperchromatic. The cytoplasm was indistinct. In some sections, there was a tendency toward rosette arrangement of the cells.

Summary Sympathetic neuroblastoma with metastases to lymph nodes, liver, lungs and lumbar vertebrae.

CASE 2—History—H. N., a white girl aged 4½ years, was admitted Aug. 24, 1934, for pain in the epigastrium and over the upper part of the thighs. The family history was irrelevant. No history of the usual childhood diseases was elicited.

During April 1934 the patient complained of pain in the upper part of the thighs. Shortly afterward she displayed a marked loss of appetite, which recently had become very poor. She played little after the onset of her illness. Some loss of weight

Fig. 3 (case 2)—Increased intracranial pressure with infiltration of the bones of the skull and face.

was noted. An abdominal mass was noted in May 1934 by a physician who administered roentgen therapy over it (dosage factors not known).

Examination—The child was pale and undernourished, with a large abdominal mass presenting a firm nodular outline chiefly in the midabdomen above the umbilicus. There was generalized glandular enlargement. Marked facial palsy was observed on the left. The tongue was protruded in the midline. The left pupil was larger than the right but both reacted to light and in accommodation. A localized edematous swelling was present in the midfrontal area to which two veins con-

verged and became quite prominent when the child cried. There was impaired resonance over both axillae. The examination otherwise gave negative results.

The Wassermann reaction was negative. A blood count showed red cells 1,610,000 and white cells 4,350 with polymorphonuclears 82 per cent, small mononuclears 17 per cent and hemoglobin 6 Gm per hundred cubic centimeters. Biopsy of an inguinal gland suggested lymphoblastoma.

The bones of the skull and face showed a finely granular type of osteoporosis suggesting infiltration of an unusual type.

There was evidence of increased intracranial pressure with widening of the coronal suture. In the chest there was evidence of pleurisy, with an effusion on the right side. The flat bones of the pelvis showed evidence of an infiltrative process similar to the changes in the skull. The long bones were the seat of an erosive process, which was noted especially along the medial borders of the diaphyses and was more prominent at the proximal ends. There was also evidence of infiltration, with beginning decalcification, throughout the shafts of some of the long bones. There was periosteal elevation, especially along the femurs.

Fig. 4 (case 2)—Granular type of infiltration of both humeri and the bones of the thorax. There is pleural thickening with fluid in the right side of the chest.

Röntgen Therapy—Roentgen therapy was administered over the epigastrium, cervical glands, axillae and forehead. The factors used were 195 kilovolts, 50 cm focal skin distance, 0.5 mm copper and 1 mm aluminum filtration. From 4.0 to 600 roentgens was administered over the various areas. After the high voltage therapy there was only slight regression in the size of the abdominal tumor. The child's appetite improved somewhat, but she continued to lose ground and died October 14.

Postmortem Examination—The liver was enlarged and there were multiple friable, reddish brown tumor masses around the hilus. In the region of the adrenals there was a large tumor mass extending to either side of the spine and surrounding the aorta and the celiac axis. It involved the adrenals, pancreas and adjacent lymph nodes. There was also involvement of the lumbar vertebrae. The tumor was composed of round or oval cells which varied in size and shape. There was a small amount of cytoplasm. The nuclei were large and vesicular with numerous nucleoli. There was a fine reticulum between the cells. The cells were grouped roughly into large alveoli and these were separated by dense fibrous trabeculae. No rosettes were seen.

Summary Sympathetic neuroblastoma arising in the medulla of the adrenals, with metastases to the pancreas, adjacent lymph nodes, liver and bone marrow.

CASE 3—History—J. B., a white man aged 26, was admitted Nov. 24, 1923, because of aching pain in the neck and nervousness. The family history was irrelevant. The patient was well until four months before admission. His neck suddenly became stiff and remained so for ten days. The stiffness recurred several times, and one day he became dizzy, with palpitation of the heart, dyspnea and pain in the region of the bladder. Afterward the pain in the neck recurred and he suffered occasionally from generalized pains throughout the body. His symptoms became worse at night. There was a history of night sweats, fever and tachycardia at times.

Examination—On admission the patient was well developed and moderately nourished with some pallor. The posterior auricular glands were enlarged, and there was a mass under and posterior to the left ear. The chest was clear. No masses were felt in the abdomen, and the liver and spleen were not palpable. The spine was rigid and, on bending toward the patient moved it as a unit. On further examination this manner of bending was felt to be a protective mechanism.

The Wassermann reaction was negative. A blood count showed red cells 3,540,000 and white cells 6,300 with polymorphonuclears 74 per cent, small lymphocytes 23 per cent, large lymphocytes 1 per cent and transitionals 2 per cent. The basal metabolic rate was +46 and the urine normal.

The spine showed a suggestion of a destructive process in the second cervical vertebra.

Clinical Course—Surgical exploration of the mass beneath the left jaw was done. A soft mass without any definite capsule was found near the vertebral column. Most of this was removed. The tumor appeared to be intimately connected with the body of the second cervical vertebra. The pathologic report was sympathetic neuroblastoma.

Radium pricks were applied over the area of the tumor. A total of 6,000 mg. hours filtered through 2 mm. of lead caused complete disappearance of the tumor to palpation.

Later the patient gradually declined, with increasing anemia and pain in the legs and back. The spleen became palpable. Several of the dorsal vertebrae showed roentgenologic evidence of metastatic lesions, with decalcification and subsequent compression of the bodies anteriorly. Death occurred June 2, 1924.

Postmortem Examination—A tumor nodule 8 mm. in diameter was observed in the spleen. Several nodules were present in the liver. Both adrenals were enlarged and on section the usual brownish yellow tissue was entirely replaced by soft, friable, grayish tumor tissue. The kidneys were normal. Many tumor nodules were found in the vertebrae throughout the spine. The ribs were also involved and there were pathologic fractures present.

Impression Sympathetic neuroblastoma primary in the adrenal, with metastasis to the ribs, spine, spleen, liver and lymph glands.

SUMMARY

In three cases of sympathetic neuroblastoma, radiotherapy caused only temporary improvement. I believe that radiotherapy is of no avail in such cases if there is evidence of metastases. The disease quickly assumes a generalized form and causes a rapid decline and the death of the patient regardless of the treatment employed.

ABSTRACT OF DISCUSSION

DR MERRILL C. SOSMAN, Boston. I am sorry that Dr. Vogt is not here but I think I can speak for him and emphasize the three ideas that he has brought out in the clinics and conferences in Boston. He has had a large experience with this type of tumor. The first one is that a similar appearance, which is seen in the parietal region of the skull in children and in young adults is a perfectly normal phenomenon and is due to the digitations of the sagittal suture between the two parts of the parietal bone. In sympathetic neuroblastoma there is an extension beyond the outer table due to the irritation of the periosteum by the tumor going through the bone. The second fact brought out in his experience is that these tumors are not very radiosensitive. The best we have been able to accomplish is only a mild amelioration. The third point is that this tumor, or this appearance of the bones, may be very exactly imitated by leukemia. In children who have leukemia (and often a leukemia unrecognizable by the blood picture, the so-called aleukemic leukemia) one will find that same area of osteoporosis and little areas which will exactly simulate this sympathetic neuroblastoma. In my experience the leukemia more commonly produces this radiographic appearance than the sympathetic neuroblastoma. These may be seen in the long bones without the skull changes, and without the history I would rather take a chance and call it aleukemic leukemia.

DR COLIN MACDONALD, Melbourne, Australia. During the twelve years that I have been radiologist in the Children's Hospital in Melbourne, where we have what we think is an alert clinical and pathologic staff, we have found only four cases which measured up to satisfactory criteria of Ewing's tumor. But during the last three or four years we have shown adults a condition in the long bones which gives an x-ray picture just like Ewing's tumor but in which our pathologist,

after careful search, has been able to show the rosette histology. As the result of seeing the rosette forms, he searched carefully the adrenal area and has been able to discover a typical neuroblastoma there. We get the typical thickening in the bones, characteristic of Ewing's tumor, but in half a dozen of these careful search has shown in addition to these anaplastic neuroblastomas, which might be thought to be Ewing's sarcoma, this rosette formation. That leads to our conclusion that some of the Ewing's tumors might really be metastatic neuroblastoma. This work has been done by Dr. Rupert Willis. During the last year, he has published a book called 'The Spread of Tumors in the Human Body,' the perusal for which I would commend to my colleagues here.

DR RALPH E. MYERS, Oklahoma City. Dr. Doub has made a valuable contribution to this subject. I am glad he has brought it to our attention again, because I well remember that the first case with which I was confronted ended fatally before I knew what it was. If one has once recognized a case, it is fairly easy to diagnose a second time, but, on the other hand, if one knows nothing about it, it is a very mystifying type of tumor. It appears to me this disease must be more common than the few cases reported seem to indicate, because in my rather limited experience I have had four of them. In one case there was so much protrusion of the eyeballs as to cause necrosis. This was a horrible condition not only for the child but also for the parents. While radiotherapy does not contribute much to the length of life, I believe this condition of the eyes can be prevented. In the two cases which I have treated it has been possible to return the eyes to their normal position and there was no necrosis of the eyeballs. The radiotherapist should endeavor to do at least this much for the patient and the parents.

DR JOHN T. MURPHY, Toledo, Ohio. It is precarious at the present time to state the roentgen dosage given in the treatment of cases a few years back, because we have found by experience that much larger doses are tolerated and that the results are primarily better when these larger amounts are used.

DR HOWARD P. DOUB, Detroit. Dr. MacDonald's remarks with regard to Ewing's sarcoma are pertinent. The neuroblastomas are much more widely disseminated than in the case of Ewing's tumor and also have a somewhat different appearance. The early metastases of the neuroblastomas are demonstrated by the fact that in the cases that we reported the average duration of life was only four and one third months of life from the time we first observed them. The massive doses of x-ray therapy as proposed by Dr. Murphy constitute the correct method of treatment when the disease is localized and when it occurs in a portion of the body where other vital structures will not be irreparably damaged. In the neuroblastomas the disease is so widespread that this massive irradiation is not feasible. The differential diagnosis has been discussed by Dr. Sosman. I did not bring this out in the paper, but two years ago Dr. Hartman and I discussed it before this section in a paper on the roentgen diagnosis of the leukemias and allied conditions. Some of the leukemias and chloroma have very similar x-ray appearances. Some of the changes in chloroma almost exactly simulate those in neuroblastoma, especially the changes along the medial borders of the upper humerus. Some of the roentgen changes would suggest that they are closely allied in their pathology.

A Valuable Experience—One of our highly trained young physicians, long-time resident in a teaching hospital, recently confessed to me that he had just been through one of the most valuable experiences of his ten years of medical study. He had passed his summer on an island where was a large summer community and in the absence of any local physician he had volunteered to hold office hours and prescribe for the needs of his fellow sojourners, his principal armament being a thermometer, his microscope, some bandages, and a few simple drugs. Never before had his powers of observation and his common sense been so thoroughly exercised.—Cushing Harvey, *Consecratio Medici and Other Papers*. Boston: Little, Brown & Co., 1928.

Clinical Notes, Suggestions and New Instruments

LYCOPodium GRANULOMA RESULTING FROM THE USE OF ANAL SUPPOSITORIES

WILLIAM ANTOPOL M.D. AND CHARLES ROBBINS M.D.
NEWARK, N. J.

In 1933¹ five cases of lycopodium granuloma were reported. In these instances the spores of lycopodium clavatum an ingredient of dusting powder used for gloves, had been introduced into the operative field in the course of surgical procedure. These acted as foreign bodies and gave rise to indolent chronic postoperative inflammatory reactions at the original operative site and necessitated secondary operations at a subsequent date. Six similar cases, in which the spores were also introduced during operative procedures were described by Erb² in 1935.

In the original communication¹ it was shown that this substance either impeded the abatement of the existing condition or gave rise to additional complicating factors, and inferentially the use of lycopodium spores as a component of dusting powder on operative implements was cautioned against.

Since that time another instance of lycopodium granuloma has been encountered in which the mode of introduction varied from the modes originally described.

A white woman, aged 33 complained of rectal pain and drainage from the anus and was admitted to the Newark Beth

Lycopodium spore within a granulomatous area (Ziehl-Neelsen stain)

Israel Hospital in March 1935. At this time an external hemorrhoidectomy was performed. Tissue examination revealed external hemorrhoids with no other significant changes. In October, hemorrhoids were again removed at another hospital and these showed 'normal epidermis and fibrous stroma' superficial infiltration with lymphocytes. There was no improvement of symptoms, and the pain and drainage from the rectum continued. In December a fistula in ano was resected and microscopic examination revealed both an acute inflammatory and a chronic granulomatous reaction composed for the most part of plasma cells epithelioid cells occasional multinucleated giant cells eosinophils monocytes and fibroblasts in addition to the spores of lycopodium. Some of the spores were engulfed in foreign body giant cells, shown in the accompanying illustration.

Since the spores of lycopodium were not employed at either hospital in which the operations were done the mode of intro-

duction of the irritating agent remained obscure. When the patient was questioned closely, however, a history of continued use of anal suppositories was elicited. These were frequently employed after the first operation because of pain. On further investigation it was ascertained that the apothecary who compounded these suppositories used the spores of lycopodium for dusting in order to prevent adhesion to the wrapper. The patient was kept under strict observation, and measures were taken to preclude the possibility of reintroduction of spores. The wound healed rapidly and at the present writing fifteen months after the last operation, there has been no recurrence of symptoms.

SUMMARY

1 A case of lycopodium granuloma was seen in which the spores had been transferred from the surface of anal suppositories into an hemorrhoidectomy wound.

2 This case presents another instance in which it is shown that the use of lycopodium spores in the region of open wounds is not entirely innocuous.

NEOPLASTIC INVOLVEMENT OF THE HEART

TWO CASES DIAGNOSED BEFORE DEATH

DONALD S. SMITH M.D. ANN ARBOR, MICH.
Instructor in Internal Medicine University Hospital

Tumors of the heart and pericardium are rare as either secondary or primary growths. Still rarer is the opportunity to see this type of case and to diagnose it during life. Two such cases were admitted to the medical wards of the University Hospital during the first four months of 1936 and in both of them the correct diagnosis was made. The literature reveals only five cases of secondary tumors of the heart diagnosed before death. Three of these were diagnosed on the basis of cardiac irregularity in patients with extensive neoplastic involvement of other regions of the body.¹ One patient was a young girl in whom symptoms of cardiac embarrassment developed some time after the removal of a sarcoma of the lower extremity.² To this group of cases are added the two reported here.

REPORT OF CASES

CASE 1—History—A white woman aged 31, was admitted to the medical service of the University Hospital with the history that two years before a wartlike lesion behind the right ear had been cauterized, after which she was given roentgen therapy to the area. This was followed by the development of lumps in various parts of the body with resolution of a few after treatment. For one month prior to admission she had noted increasing pallor and dyspnea on exertion. Two months prior to admission there was an attack of a pleuritic type of pain associated with a febrile illness. This lasted one week and there was hemoptysis on one occasion and slight cough. Other history was noncontributory.

Examination—The only positive manifestations found on physical examination were multiple subcutaneous masses slight dulness at the base of the right lung and a pericardial friction rub. The laboratory studies revealed a leukocytosis of 73,400 with 93 per cent polymorphonuclears. Roentgenographic study of the chest showed obvious cardiac enlargement with marked broadening of the transverse diameter very marked increase in bronchovascular markings with apparently closely associated infiltrative changes in the lung along the main bronchial distribution in the right base. These changes were believed to be due either to an inflammatory process or to neoplastic invasion (fig. 1). The course was essentially downhill, intractable pain being present from the neoplastic nodules. After approximately ten days in the hospital the friction rub had disappeared. The clinical impression was probable melanoblastoma with metastases to the right lung, pericardium, heart, liver and subcutaneous tissue.

2 Erb I. H. *Surg Gynec & Obst* 60: 40 (Jan) 1935.

Postmortem Examination—The pathologic diagnosis was metastatic melanotic melanoblastoma involving the liver, lungs, mediastinum, heart, adrenals, subcutaneous tissue, sternum, ribs, vertebral bodies and multiple lymph nodes throughout the body. Neoplastic polypoid thrombi were found in the left ventricle attached to the mitral leaflet. Examination of the heart revealed a fibrous exudate externally on the right and the pericardial sac was almost completely obliterated. An attempt at separation of the two layers of the pericardium revealed fibrous union as well as extensive infiltration by soft dark gray red masses of neoplasm. This was apparently in direct continuity with a supradiaphragmatic mass found in the lower lobe of the right lung.

CASE 2—History—A white woman aged 25 admitted to the medical service, complained of a mass in the right upper quadrant and shortness of breath. This mass had been present for four months, increasing from the size of a lemon to that of a watermelon. During the month prior to admission she had had increasing shortness of breath. There had been chills and fever to 102 F associated with migratory muscle pains starting in the neck, radiating down the right arm and to the right calf. She had noted increasing pallor associated with dyspnea. For two weeks prior to admission edema of the ankles and face had been present. There had been a slight cough for a week prior to admission. The patient stated that she was able to lie on the right side with ease but became dyspneic when lying on the left side. There was no history of antecedent rheumatic infection.

Examination—On admission the patient was dyspneic and pale, with puffiness of the face. The heart was markedly enlarged to the right of the parasternal line and the left border of dullness was at the anterior axillary line. There was a systolic thrill at the apex and at the apex and in the second intercostal space on the left auscultation revealed a high pitched blowing systolic murmur and a loud low pitched diastolic murmur. The pulmonary second sound was accentuated. Abdominal examination revealed a huge tumor extending 12 cm below the right costal margin and to a point well below the umbilicus. Laboratory studies revealed only a severe secondary anemia.

The x-ray examination of the chest showed gross cardiac enlargement of indeterminate cause and patchy disseminated infiltration of both lung fields (fig 2). The electrocardiogram showed the heart rate to be 120 per minute with atrioventricular rhythm, abnormally small complexes and inverted T waves in all leads (? digitalis effect).

The clinical diagnosis on admission was neoplasm of the liver and rheumatic heart disease with mitral stenosis. The latter diagnosis was later changed to neoplasm involving chiefly the right side of the heart. This diagnosis was based on the abdominal neoplasm the

Fig 1 (case 1)—Area of increased density along the right border of the heart

marked abnormality in the cardiac silhouette in the x-ray film, the failure to respond to digitalis therapy, the abnormality in the electrocardiographic tracings and the absence of any obvious cause for the cardiac enlargement. It was thought that a right auricular tumor involving the sino auricular node might explain the abnormal cardiac rhythm.

Postmortem Examination—The pathologic diagnosis was primary spindle cell sarcoma (? hemangiosarcoma) of the liver with metastases to the liver, heart, lungs, lymph nodes, kidney, adrenals and right ilium. The heart was grossly enlarged, weighing 630 Gm. When the pericardial adhesions were cut through there were nodular and hemorrhagic areas over the right auricle and intraventricular septum, most pronounced about the pulmonary artery. There was no abnormality of the mitral valve. Within the intraventricular septum and about

the coronaries were found areas of whitish yellow neoplastic tissue. The right auricle was markedly enlarged, the enlargement being due to many nodules, apparently within the auricle. Extending out to the base of the pulmonary valve in the posterior area was a thickened mass 10 by 20 mm showing similar neoplastic areas.

COMMENT

It is not my purpose in this paper to give a summary of all the literature to date concerning primary or secondary tumors of the heart, but it would seem proper to present previous observations in the literature that are of help in diagnosing such a condition. In the most comprehensive article on tumors of the heart and pericardium, written by Yater in 1931³ there is a classification well worth reviewing. He groups these cases logically into those in which the clinical type is not suggestive of tumor of the heart and those in which the type is suggestive of such a diagnosis. Under the first type he groups those in which there is sudden death, terminal cardiac embarrassment, symptoms of congestive heart failure or lastly symptoms suggestive of subacute bacterial endocarditis. In the second group there are

Fig 2 (case 2)—Gross cardiac enlargement with prominence of the right auricle

various abnormalities such as heart block, symptoms referable to the location of the tumor other than heart block, symptoms of cardiac dysfunction developing without apparent cause in a patient with a known malignant process, accumulation of hemorrhagic fluid in the pericardial sac and, lastly, suggestive x-ray signs. Yater believes that in a certain percentage of cases symptoms of congestive heart failure may develop and that when the clinician is unable to find other etiologic agents he may be justified in placing it in the group of metastatic neoplastic involvement.

As regards the physical changes in neoplastic involvement of the heart perhaps one of the most frequent is the presence of a murmur believed typical of mitral stenosis. This is often due to a pedunculated tumor of the right or left auricle causing a functional stenosis of the tricuspid or mitral orifice with certain changes in position. Ludwig⁴ presents a case in which mitral stenosis was diagnosed and collected twenty others from the literature in which mitral stenosis was suspected during life and autopsy showed neoplasm involving the auricular muscle.

In the group of changes referable to the heart directly one of the most important is abnormality disclosed by the electrocardiogram. Yater believes that heart block is one condition in which metastatic neoplasm should be considered as a possible etiologic agent. Fishberg¹ has presented three cases of abnormal rhythm in which the diagnosis of neoplastic involvement of the heart was made before death. Two of his cases presented auricular fibrillation and one auricular flutter.

In the first of the two cases presented here the diagnosis was suspected because of the pericardial friction rub at the base of the heart. The diagnosis was supported by the finding on x-ray examination of an area of increased density along the right border of the heart which extended into the pulmonary parenchyma. The possibility of a neoplastic thrombus in the heart was also considered in this case because of the widespread metastases, including subcutaneous metastases which were apparently hematogenous in origin. In the second case the diagnosis was suspected because of the history suggesting neoplastic involvement of the liver coupled with the sudden

³ Yater, W. M. Tumors of the Heart and Pericardium. Pathology, Symptomatology and Report of Nine Cases. Arch. Int. Med. 48: 627-666 (Oct.) 1931.

⁴ Ludwig, cited by Gilchrist, A. R. and Millar, W. G. Paroxysmal Auricular Tachycardia with Primary Tumor (Myxoma) with Pathological Report. Edinburgh M. J. 42: 243-258 (April) 1936.

onset of symptoms of cardiac failure. Here the physical examination revealed a diastolic murmur at the apex and along the left border of the sternum. This was at first thought to be a mitral murmur, but no history of rheumatic infection could be elicited and after the x-ray film was seen it was felt that the murmur might well be due to an intracardiac metastatic neoplasm. This opinion was supported by the course of the patient's illness, her failure to respond to digitalis and the widespread neoplastic involvement elsewhere revealed by the x-ray examinations. The x-ray appearances were particularly suggestive of tumor involving the right side of the heart. The patient's ability to lie on the right side of the body and not on the left offered a possible explanation of the cardiac embarrassment. It was thought to be caused by pedunculated intracardiac mass. It was felt, therefore, that an antemortem diagnosis of secondary cardiac involvement was justified in both cases.

CONCLUSION

1 In the two cases of secondary involvement of the heart by malignant neoplasm there were adequate clinical and laboratory data to warrant a diagnosis before death.

2 The observations that made such a diagnosis possible were, in one case, a pericardial friction rub and, in the second case, the presence of atrioventricular rhythm revealed by the electrocardiogram, and the presence of a definite diastolic murmur which could not easily be accounted for on any other basis.

STAPHYLOCOCCIC ENDOCARDITIS SUPERIMPOSED ON SYPHILITIC AORTIC ENDOCARDITIS

ROBERT L. McMILLAN, M.D., WINSTON SALEM, N. C., AND
E. LLOYD WILBUR, M.D., DURHAM, N. C.

Bacterial infection superimposed on syphilitic endocarditis is of interest because of the paucity of proved cases reported in the literature and the rarity of the infections occurring simultaneously, although each is common as a separate entity.

Kastner¹ in 1918, Briggs² in 1922, Pineles³ in 1926 and Craven⁴ in 1932 have each reported one case proved by autopsy. Other cases have been reported which have not been proved by autopsy but which presented aortic insufficiency, blood cultures positive for *Streptococcus viridans* and positive Wassermann reactions of the blood.

Cotton,⁵ in a study of fifty cases of aortic insufficiency agrees with other authors that prior to the age of 40 rheumatic lesions predominate whereas after 40 the lesions are almost entirely syphilitic or atherosclerotic. He corroborates the well known fact that bacterial endocarditis occurs as a rule in youth or young adulthood. Bayne-Jones⁶ has emphasized the increased vascularity of the valves involved in rheumatic fever which renders these damaged valves more liable to superimposed bacterial infection. The absence of this factor in syphilitic endocarditis may account for the extremely low incidence of bacterial infection.

Clinically, the diagnosis cannot be made on the basis of demonstrable aortic regurgitation, with positive Wassermann reaction and blood culture, but must depend on previously diagnosed syphilitic endocarditis and subsequent evidence of bacterial infection of the endocardium.

REPORT OF CASE

History—J. E. R., a white man, aged 47, a painter, first seen in the Duke Hospital Medical Dispensary March 21, 1935, complained of heart trouble of five years and stomach trouble of two years' duration.

The family and marital histories were not of interest.

From the Departments of Medicine and Pathology, Duke University School of Medicine.

The past history showed excellent general health up to the onset of the present illness. There were the usual childhood diseases, typhoid in 1900 (at the age of 12), a generalized skin eruption diagnosed chickenpox in 1925 (at the age of 37) and a hemorrhoidectomy in 1934. In 1906 (at the age of 18) he had a primary chancre which was treated locally only with a dusting powder. In 1920 (at the age of 32) the Wassermann reaction of the blood was reported 4+, and he was given six injections each of arsphenamine, a bismuth compound and mercury.

He felt well until 1931, when, while exercising vigorously, he had an attack of precordial pain lasting thirty minutes associated with marked dyspnea. From this time on he noticed dyspnea on exertion and had many such attacks, which incapacitated him. Between the summer of 1934 and admission to the clinic, intermittent swelling of the feet and ankles and finally abdominal swelling developed. The precordial pain and dyspnea became progressively more severe. For the first attack of precordial pain his physician administered morphine hypodermically, and a well established addiction to the drug soon developed. The patient finally requiring 7 or 8 grains (0.45 or 0.5 Gm.) daily. It is of particular significance and interest in this case that for the last year of his life he had been giving his own injections intravenously, with poorly sterilized tap water.

Examination—The patient was large and well nourished and was in obvious respiratory distress. The head jerked with each heartbeat and all visible arteries were pulsating forcibly.

The skin was clear. The cervical, axillary and epitrochlear lymph nodes were slightly enlarged. The pupils were small round and equal and reacted to light and in accommodation. The optic fundi were normal except for marked pulsation of the arterioles. The trachea was in the midline, and no tracheal tug was felt.

The thorax showed a bulge over the precordium and an increase of the anteroposterior diameter with retraction of the costal borders on inspiration. The percussion note over the lungs was resonant, and the breath sounds were clear.

The heart was greatly enlarged, the apex being 15 cm. to the left of the midsternal line in the sixth intercostal space. There was very little enlargement to the right. The supracardiac dulness was 8 cm. The cardiac impulse was forceful and diffuse. Over the entire precordium a loud blowing systolic murmur and a murmur occupying the whole of diastole were heard. These were most intense in the second right interspace and were there accompanied by a systolic thrill. The heart rhythm was regular, with a rate of 90. The blood pressure was 170 systolic, 70 diastolic. Corrigan and capillary pulses and pistol-shot femoral sounds were prominent and equal, on the right and left.

The liver border was felt 6 cm. below the right costal margin and was tender. There was slight edema of the feet and ankles. Motor, reflex, sensory and coordination tests gave normal results.

Laboratory examination revealed hemoglobin, 11 Gm. 71 per cent of 15.5 Gm. (Sahli), red blood cells, 3,110,000, urine, no albumin, sugar, casts, red blood cells or white blood cells. The Kahn reaction was 3+.

The diagnosis at this time was syphilis of the aorta, involving all parts of the aorta from the aortic valves through the arch, aortic regurgitation, cardiac hypertrophy and dilatation with beginning congestive heart failure.

Digitalis and potassium iodide were prescribed and he was instructed to rest and return to the syphilis clinic for further treatment. However, he did not return for his treatment and was next seen December 26 in severe congestive failure and practically moribund. For two or three days previously he had had facial edema and crops of erythematous lesions. He had also had several chills and some fever.

The temperature was 37.2 C (99 F), the pulse 90 and the respiration rate 28. He was in extreme respiratory distress with Cheyne-Stokes breathing. Marked generalized edema was present.

Scattered over the skin of the face, arms, neck and thorax were numerous papular erythematous lesions that blanched slightly on pressure. The mucous membranes were very pale.

The heart was essentially as noted on the previous admission except that the supracardiac dulness was 10 cm. The blood pressure was 194 systolic, 72 diastolic.

There was marked hepatomegaly with tenderness. The spleen was not felt.

Accessory examinations revealed, hemoglobin 9 Gm. 57 per cent of 15.5 (Sabin), red blood cells 2,500,000, white blood cells, 11,000, of which 80 per cent were polymorphonuclears with a preponderance of adult forms. The Kahn reaction was 3+. The urine was dark and cloudy, with albumin 4+, acetone 1+, and an occasional red blood cell. The benzidine test was positive. The nonprotein nitrogen of the blood was 10.2, creatinine 9.2 mg. per hundred cubic centimeters, and refractive index 1.0493. The electrocardiogram showed normal sinus rhythm, intraventricular block, and left axis deviation. The spinal fluid (post mortem) gave a normal reaction with the Wassermann, the colloidal, the mastix and the Pandy test. No cells were present.

The patient became progressively worse and died December 27, twenty-four hours after admission.

The diagnosis was (1) syphilis of the aorta with fusiform aneurysm, (2) aortic regurgitation, due to syphilis with cardiac hypertrophy and congestive failure, (3) subacute glomerulonephritis, and (4) suspected bacterial endocarditis.

Autopsy.—The anatomic diagnosis with the history of morphine addiction and syphilis was as follows: Syphilitic aortitis with formation of aneurysm, syphilitic aortic endocarditis with aortic insufficiency, cardiac hypertrophy and dilatation, chronic meningitis (syphilitic), aortic and mitral vegetative endocarditis (hemolytic *Staphylococcus aureus*), embolic acute arteritis (jejunum), subacute glomerulonephritis, infected infarct of the spleen, acute splenic tumor, chronic passive congestion of the lungs and liver with thrombosis of the veins of the right forearm, and adenoma of the islands of Langerhans.

Macroscopic Observations. The body was very emaciated. There was a purplish papulovesicular rash on the neck in the

One, syphilitic in origin was characterized by a separation of the cusps at the point of attachment. The other was a series of wartlike vegetations 2 mm in diameter, close to the free edge of the cusps. On the left coronary cusp was a sessile mass 5 mm in diameter. A similar vegetation was found on the endocardium 1 cm below the posterior cusp apparently opposite the vegetations on the mitral valve. The anterior

Fig. 2—Aortic valve with vegetations and syphilitic lesions

cusp of the mitral valve had two sessile masses of vegetation located about 4 mm from the free edge. One of these was 1 cm and the other 0.5 cm in diameter. These extended through the cusp and presented on both surfaces. The mitral valve showed no thickening of the free edges of the cusps or of the chordae tendineae.

There was an aneurysm 8 cm in diameter, beginning in the sinus of Valsalva and extending 1 cm distal to the origin of the left subclavian artery. The wall of the aneurysm showed much calcification. There was a moderate amount of sclerosis in the remainder of the aorta.

The liver was enlarged, weighing 2410 Gm. The kidneys each weighed 240 Gm and had finely granular cortical surfaces in which were numerous petechial hemorrhages.

The spleen weighed 650 Gm and contained a fresh infarct measuring 6 by 5 by 10 cm. A purulent fluid oozed from the cut surface of this infarct.

Microscopic Observations. The section of the aortic valve showed much fibrous thickening. On the surface of the valve was much granulation tissue and necrotic debris in which were clouds of gram positive cocci.

The walls of the aneurysm were composed of scar tissue and particles of calcium. A few collections of round cells were seen close to the adventitia.

Clouds of gram positive cocci were found in the splenic infarct. There was a subacute glomerulonephritis and some degeneration of the epithelium of the convoluted tubules.

In the meninges there was a moderate round cell infiltration. There were some focal areas of degeneration in the brain. These were not limited to any particular areas.

An incidental finding was an adenoma of islet tissue in the pancreas. This measured 5 by 4 by 3 mm.

Postmortem culture of the spleen showed a pure growth of hemolytic *Staphylococcus aureus*. Smears of the splenic infarct showed clusters of gram-positive cocci.

SUMMARY

The case presented is the fifth recorded proved case of bacterial infection superimposed on syphilitic aortic endocarditis.

Final proof of such a case rests on autopsy and bacteriologic studies but the diagnosis may be suspected clinically in a person with syphilitic aortic insufficiency of long standing in whom manifestations of bacterial endocarditis subsequently develop.

The case cited is of further interest because of the fact that the patient was injecting unsterilized solutions into his own veins, this probably being the mode of infection.

Fig. 1—Heart and aorta with aneurysm

region of the jugular notch and on the surfaces of both forearms following the courses of the superficial veins. These lesions were discrete and well circumscribed. They did not resemble petechiae.

Each pleural cavity contained 600 cc of a clear straw-colored fluid and the peritoneal cavity contained 2,000 cc of a similar fluid.

The heart weighed 750 Gm and the aortic ring was dilated. There were two types of lesions involving the aortic valve.

POSTERO ANTERIOR X-RAY VIEW OF KNEE
IN FLEXION

EDWARD C. HOLMBLAD, M.D., CHICAGO

The accurate diagnosis of pathologic conditions of the knee joint is at its best a difficult task before operation. X-ray study has been a great aid but in some cases the pathologic

Fig. 1.—Position of patient in which the x-ray films are taken

Fig. 2.—Normal knee of man aged 25. Intercondylar notch clear, tibial spines smooth, joint surfaces smooth, margins of tibia and femur normally rounded.

condition cannot be demonstrated. In quite a few cases the clinical history is strongly suggestive of joint mice, which are not demonstrated on the usual x-ray views. The overlapping shadows of the patella hidden behind the lower portion of the femur and the knee joint ramifications on the anterior

surface of the femur are difficult to visualize on postero anterior views or anteroposterior views with the leg extended. Small or faint shadow-casting foreign bodies, "joint mice" or osteophytes are frequently not visualized. The joint surfaces are not clear sharp or well separated. The detail of the upper end of the tibia is not always sharply defined, and incomplete fractures or atypical fractures of the upper tibia extending into the joint may require the superior ability of the expert x-ray diagnostician.

It was with the hope of improving x-ray technic in this particular respect that this problem was approached.

During the past years simple knee cases have been studied in lateral and postero-anterior views. More difficult knee problem cases have prompted in addition the use of oblique views, both internal oblique and external oblique. These are sometimes called quartering views. They are especially advantageous in studying the condyles of the femur and the patella.

During the summer of 1936, views were taken on curved cassettes with the knee in flexion and the cassettes placed in the popliteal space. This resulted in considerable distortion but was an improvement in visualizing the intercondylar notch of the femur.

Fig. 3.—(man aged 57, weight 244 pounds or 111 kg.)—Tibial spine, sharp and pointed intercondylar margin of medial condyle of femur shows early osteoarthritic flapping and spur formation.

In February 1937 a new position was employed. It was designed to use the intercondylar notch of the femur for better visualization of the tibial spines and attachments of the cruciate ligaments and the knee joint. This view was taken as shown in the accompanying illustrations. It is taken postero anteriorly with the knee flexed 75 degrees, the tibia nearly paralleling the top of the table. In cases in which there is limitation of ankle motion, the foot is permitted to hang over the end of the table thereby maintaining the lower leg parallel to the top of the cassette or film.

Films in exposure envelopes or in exposure holders, films in cassettes or the Potter-Bucky technic can be used as desired to obtain the best results.

Studies of films made in these views have disclosed several distinct advantages over the usual postero anterior view in full extension.

1. There is a much better visualization of the intercondylar notch of the femur with osteoarthritic flapping frequently seen at the margins that cannot be viewed in the usual exposures.

2. It is noted that the tibial spines are brought out in a clearer profile and the troublesome overlapping shadow eliminated.

ated. In this way the attachments of the cruciate ligaments are studied and avulsion fractures of ligamentous attachments are much more readily recognized.

Fig. 4 (man aged 50)—Tibial spines are sharp and pointed both margins of intercondylar notch are markedly roughened and irregular because of osteo arthritis. A small osteophyte or joint mouse is noted near the intercondylar margin of the medial condyle of the femur.

Fig. 5 (man aged 50)—History of frequent knee joint locking, prominent tibial spines, a large osteophyte or joint mouse is demonstrated in the intercondylar notch.

3 The degree of flexion of the knee in which this view is taken permits a greater relaxation of the knee joint and therefore widens the joint spaces between the tibia and the femur giving a much clearer study of the joint and the joint surfaces of the tibia and femur.

4 When the upper and anterior portion of the tibia is the site of special study, this view yields much clearer and more diagnostic detail. It is a fundamental principle of x-ray technique that the closer a bone can be brought to the film the clearer the bone detail and sharper the x-ray shadows. With the leg extended the patella lies between the tibia and the film. With the knee flexed the tibia is permitted to rest directly on the film.

5 In this view the distal third of the patella is visualized in the anteroposterior view and the site of attachment of the infrapatellar tendon is readily seen.

6 Because of a better visualization with the knee joint spaces widened and the intercondylar notch visualized, osteophytes, joint mice, loose bodies and foreign bodies are much more easily seen and demonstrated.

7 In cases in which there is lack of full extension such as flexion deformity of the knee with partial or complete ankylosis this view can easily be taken. It therefore affords an excellent opportunity to study such knee joints for diagnosis and also in anticipation of corrective surgery as arthrodesis.

8 It gives an anteroposterior profile study of that portion of the joint surface on the condyles of the femur lying posteriorly. In cases of osteochondritis dissecans the crater areas on the condyles can be seen.

9 This view does not require any special apparatus. It is so simple that it can be done in any place equipped to take roentgenograms. A word of caution is given to those not yet provided with shock proof equipment. The danger of having an exposed wire within sparking distance of the buttocks should be avoided. This can be done by raising the tube and increasing the distance from the tube to the film.

UNUSUAL ASPECTS OF HYPERTHYROIDISM

CLINICAL LECTURE AT ATLANTIC CITY SESSION

C. W. DOWDEN, M.D.

LOUISVILLE, KY.

The symptoms and signs which characterize the onset and course of typical hyperthyroidism are too well known to be repeated. For the purpose of this discussion, I shall consider the effect of an increased amount of thyroxine in the circulating blood and shall not attempt to differentiate between exophthalmic goiter and the toxic adenoma of Plummer. Although there is some difference in the onset and severity of symptoms of these two types, the effect in general on the nutritional state, the nervous and circulatory systems and the reaction of the body are the same. Unquestionably there has been and still is a tendency to depend largely on the basal metabolic rate for diagnosis. In my section of the country, at least according to my experience, in a large number of determinations an overwhelming majority are on the minus side and rates of from minus 10 to minus 15 per cent are not infrequent for persons with conditions not associated with the thyroid and with normal quantities of blood cholesterol. It must be evident, therefore, that when hyperthyroidism or hypermetabolism occurs in this group, even with a 20 per cent increase, the figures for the basal metabolism will fall within the established normal range. It is by no

Dr. Morris Flexner and Dr. A. B. Loveman provided cases 4 and 6 respectively. Dr. A. J. Miller furnished the pathologic reports.

Read in the General Scientific Meetings at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 7, 1937.

means a fault of the apparatus but is the fault of the physician in not determining the patient's normal rate and in failing to evaluate properly the state of nutrition and the symptoms particularly referable to the nervous and circulatory systems. Since iodine is anticalorigenic, it can usually be depended on to determine the normal metabolic rate when there is any doubt. While I approve of the present attitude concerning the use of iodine, my own experience has convinced me that in selected cases it may be employed successfully in the treatment of hyperthyroidism, and by its intermittent use one will continue to get its anticalorigenic effect.

CASE 1—A man aged 32, examined in December 1927, had suffered for eleven years from palpitation, emotional instability, general weakness, loss of weight in spite of a splendid appetite, dizziness and fainting attacks. The pulse rate was 80 and the blood pressure 120 systolic 80 diastolic. At that time he had a typical duodenal ulcer, which was confirmed radiographically. In December 1929 the symptoms of ulcer had disappeared, but the other symptoms referable to the nervous system had increased. The pulse rate was 100 and the blood pressure 128 systolic, 70 diastolic. In October 1931 there was a marked increase in all the symptoms and in spite of the splendid appetite there was a loss of 20 pounds (9 Kg.) in weight. The thyroid was now definitely enlarged and nodular. A bruit was heard over the gland. There were marked pulsation in the vessels of the neck and a fine tremor of the fingers. The pulse rate was 100 and the blood pressure 160 systolic, 80 diastolic. There were no ocular signs. The electrocardiogram was normal. The basal metabolic rate was minus 7.7 per cent. Two months later, after the patient had taken 5 drops of compound solution of iodine daily, there was a gain of 10 pounds (4.5 Kg.) in weight, the pulse rate varied from 76 to 90 and the blood pressure was 160 systolic 88 diastolic. He was stronger and not so easily excited or nervous.

In April 1932 marked heat intolerance developed in spite of the fact that the patient had spent three years on the deserts of Mexico without discomfort. Now it was almost impossible for him to enter a moderately warm room. The administration of iodine was continued, and by July 1932 he had gained another 10 pounds (4.5 Kg.), or 20 pounds (9 Kg.) in all, the pulse rate was 84, although he occasionally had palpitation, the blood pressure was 150 systolic 80 diastolic, the thyroid was unchanged. In September 1932, the administration of iodine having been discontinued he was again nervous and emotionally unstable, the pulse rate was 104, the blood pressure 158 systolic, 80 diastolic and the basal metabolic rate plus 7.2 per cent. Iodine was then taken intermittently and he was not seen again until January 1934, immediately after completing a two weeks period on iodine. This time the pulse rate was 70, the basal metabolic rate was minus 12.5 per cent, a drop of practically 20 points, which was looked on as a positive response to iodine. The iodine was then taken for two weeks of every four, and on Feb. 26, 1934 after a period without iodine the basal metabolic rate was minus 11.8 per cent, the pulse 76 and the blood pressure 120 systolic, 70 diastolic. He had regained his lost weight, the nervous symptoms had subsided and there remained only the tremor of the fingers and the palpable thyroid gland. The administration of iodine was discontinued and a year later there had been no return of symptoms.

Thus, then, is a fairly typical example of the usual course of toxic adenoma. The basal metabolic rate was misleading until the normal rate was determined by the use of iodine and found to be in the neighborhood of minus 12 per cent. An increase of 20 per cent, which would be expected, made it only plus 7 per cent.

Occasionally, exophthalmos and the directly associated signs are the only indication of exophthalmic goiter.

CASE 2—A man, aged 36, an executive seen in June 1922 had had extreme bilateral exophthalmos for six months. He was not nervous or emotionally unstable, the appetite was normal, and the weight had been constant for eight years. There was no heat intolerance, diarrhea or in fact any symptom referable to the various systems of the body.

Occasionally, however, it is necessary to discount such a history, especially coming from men. Objectively, there was marked exophthalmos, with the sclera plainly seen above the cornea, there were lid lag, widening of the orbital slits, infrequent winking and poor convergence. The pulse rate was 60 and the blood pressure 122 systolic, 62 diastolic, there was definite tremor of the fingers, but the thyroid could not be palpated. The basal metabolic rate was plus 20 per cent. From June 1, 1922, to April 1, 1923, the patient had thirteen x-ray exposures over the gland, and during this time six determinations of the basal metabolism were made. The values ranged from plus 22 to plus 10 per cent, the pulse rate from 74 to 60 and the weight from 124 to 133 pounds (56 to 60 Kg.) at the completion of treatment.

Five years later the ocular signs had perceptibly increased but with the exception of palpitation following strenuous exertion no other symptoms had appeared. The pulse rate was 68, the blood pressure 118 systolic, 72 diastolic, and the basal metabolic rate plus 29 per cent. Compound solution of iodine, 10 minims (0.6 cc.) twice daily, was prescribed, and the basal metabolic rate was promptly reduced from plus 25.5 per cent to plus 17 to minus 9 and, by September 1927 to minus 14.5 per cent, the pulse rate was reduced from 76 to 60, and the weight was increased from 128 to 138 pounds (58 to 62 Kg.). In October 1927 a subtotal thyroidectomy was done, 12 Gm. of tissue being removed. Microscopic examination showed that this was hypertrophic parenchymatous thyroid tissue. It was noted at operation that each lobe was approximately normal in size. For a period of four months thyroid was administered in varying doses.

The patient was not seen again for six years, at which time there was no more protrusion of the eyeballs than is often seen in normal persons, but he continued to have the irregular heart action after exercise and also the tremor of the fingers. The weight was 150 pounds (68 Kg.), the pulse rate 56, the blood pressure 128 systolic, 80 diastolic and the basal rate minus 13 per cent. The thyroidectomy had relieved the exophthalmos but did not influence the other minor toxic symptoms.

Symptoms typical of thyrotoxicosis, even to the initial rise of the basal metabolic rate, are often seen with nervous disorders of the autonomic imbalance group. When this is the case, the diagnosis is not always simple. Unfortunately, some patients sacrifice portions of the thyroid, thus adding, later on, to their nervous instability the symptoms of myxedema. Others are denied thyroidectomy because the associated hyperthyroidism is not recognized. Rest and sedation usually restore the basal metabolism and the blood pressure to normal in the nervous person, but the thyrotoxic person is not thus relieved until iodine is administered, which promptly alleviates most of the symptoms. One may observe two other differences which are adaptable to clinical demonstration and which in my opinion have not been sufficiently stressed. First, the pulse rate in the autonomic group does not parallel the basal metabolic rate as it does in the thyrotoxic group, and, second, the pulse pressure is not wide as it practically always is in the thyrotoxic group.

Since popularization of the basal metabolic rate among members of the medical profession, there has been a tremendous stimulus to thyroid feeding for practically all conditions associated with a lowered metabolic rate, especially obesity and exhaustion. Frequently it is very effective, particularly if there is hypercholesterolemia. Often it is indefinitely continued, until the characteristic signs and symptoms of hyperthyroidism appear.

CASE 3—A woman aged 44 was suffering from extreme nervousness, palpitation, tremor, loss of weight and such heat intolerance that she would faint on entering a warm room. She had a stimulated mental attitude and increased perspiration. The pulse rate was 120 and the basal metabolic rate was plus 10 per cent. It was rather hesitatingly admitted that fifteen years previously very refractory nausea and vomiting had promptly responded to the daily administration of 5 grains

(0.32 Gm) of dried thyroid gland that had been prescribed when the basal metabolic rate was found to be 27 per cent below the normal. She felt that the administration of such a wonderful drug should be continued, and it was in the same dose, for fifteen years.

It is interesting to note that the blood cholesterol content was 350 mg per hundred cubic centimeters of blood, suggesting that this condition may persist even after control of the hypothyroid symptoms. Needless to say, such patients do not respond to the administration of iodine, because the action of iodine is not on the circulating hormone but on the gland itself. Simple withdrawal of the thyroid or regulation of the dose is all that is necessary.

Just the reverse is rather infrequently seen, that is, toxic goiter ending spontaneously in hypothyroidism or myxedema. It is not always possible to obtain a history of earlier toxic symptoms, as the following case shows.

CASE 4—Mrs. D., aged 43, had been told one year previously that she had a low metabolic rate, and thyroid was prescribed. On admission to the hospital she stated that in spite of this

7 per cent and the pulse rate remained at 58. The blood cholesterol content was 136 mg per hundred cubic centimeters.

Truly, this was a mixed picture, and probably the dismissed diagnosis of disthyroidism was correct. But probably also at an earlier age the patient had had thyrotoxicosis that was not suspected and ended spontaneously in what was at least symptomatic hypothyroidism.

When hypothyroidism and postinfluenzal parkinsonism appear together, the diagnosis is frequently confusing. Changes in the motor and vegetative nervous systems are common to the two, as are also tachycardia, nervousness and loss of weight.

CASE 5—A man aged 38, had for eleven years been extremely nervous with frequent attacks of vertigo, occasional diplopia and tachycardia. He had muscular weakness, heat intolerance and an oculogyric crisis. In spite of a splendid appetite he had lost 20 pounds (9 Kg) in weight. Fourteen years previously he had had a severe influenzal infection. The physical examination revealed a bilaterally enlarged soft thyroid gland, a vaso motor flush, pulsating neck vessels and a marked coarse tremor.

Fig. 1 (case 4)—The epithelium is cuboid save for some areas where it is still columnar. There is some papillary projection into the lumens. The stroma is increasing in some areas it is very dense and is infiltrated with lymphocytes. In some areas the structure is fetal in type.

she had become progressively more nervous and had gained weight at an amazing rate though constantly suffering from anorexia. No amount of sleep seemed to cure her exhaustion. She complained of a mass in her throat and increasing difficulty in swallowing, particularly after excitement. She was not constipated, and there was no heat intolerance but rather the hands were always cold and wet with moisture. There was no dryness of the skin or hair and no history of earlier symptoms of toxic goiter or familial goiter.

The results of the examination were unimportant except for a pulse rate of only 62 and a basal metabolic rate of minus 22 per cent. However, because of the obstructive features a subtotal thyroidectomy was decided on and the entire right lobe and isthmus and three fourths of the left lobe were removed, totaling 12 Gm in weight. No coarse nodules were seen. Microscopic examination showed a marked increase in stroma and a small amount of lymphocytic infiltration. There were numerous small nodules of thyroid tissue growth some containing papillary masses. The epithelium was chiefly cuboid or low columnar in type. The acini were small and filled with normal staining colloid, except for a few water areas infiltrated with monocytes. In a few of the masses fetal structures were seen. The impression was of partial involution of a hyperplastic and hyperactive gland. A month later the patient was free from her symptoms and, although she had taken no thyroid, the weight had been reduced from 154 to 149 pounds (70 to 67 Kg), the basal metabolic rate had increased to minus

of the fingers. There was moderate exophthalmos, with lid lag and poor convergence. There was also definite propulsion. The electrocardiogram showed preponderance of the left ventricle and simple tachycardia. The pulse rate was 100, the basal metabolic rate plus 24, the blood pressure 150 systolic, 80 diastolic and the weight 165 pounds (75 Kg).

For diagnostic purposes the patient was told to return home and take compound solution of iodine in 10 minims (0.6 cc) doses three times daily for ten days and return to the hospital for further examination. This he did and it was surprising to find a pulse rate of 120, a basal metabolic rate of plus 25 per cent and all his symptoms greatly increased. As if it had not previously occurred to him, he then ventured the information that he had been taking iodine in 20 drop doses three times daily for over two years. Again it seems to be characteristic of men particularly to withhold important clinical data. The administration of iodine was immediately discontinued and after five days rest and the use of sedatives the patient was symptom free, with a pulse rate of 60 and a blood pressure of 120 systolic, 80 diastolic and a basal metabolic rate of plus 12 per cent. I thought I was seeing my first case of iodine hyperthyroidism. He was then allowed to return home with instructions to rest, take sedatives and certainly to take no more iodine. When he returned fifteen days later all thought of iodine hyperthyroidism was dispelled. He had a return of all his symptoms, greatly exaggerated with a basal metabolic rate of plus 37 per cent, a pulse rate of 120 and a blood pressure of 160 systolic, 90 diastolic.

Seven days later a subtotal thyroidectomy was done, and the pathologic report was hyperplastic goiter with involution. Iodine was given intermittently and the administration was continued for six months, during which there was steady improvement of all the thyrotoxic symptoms. A year later the basal metabolic rate was minus 5 per cent, the pulse rate was 78, the blood pressure was 156 systolic 80 diastolic and the weight was 170 pounds (77 Kg). The patient still complained of vertigo, double vision and slight nervousness, but he was otherwise greatly improved and working daily as a civil engineer.

Before using iodine for diagnostic purposes it would seem rather important to determine whether the patient has been taking iodine, particularly as iodized salt.

Hyperthyroidism is not infrequently associated with hypertensive cardiovascular disease and, when congestive heart failure is compelling attention and there is no goiter, exophthalmos or tremor, the diagnosis is likely to be overlooked. A careful observer will find, however, that in addition to the unmistakable signs of cardiac failure there is a marked stimulation of the mental attitude, great fatigability, loss of weight and

unusual to find cutaneous diseases associated with thyrotoxicosis, although localized nodular swellings on the anterior aspects of the lower part of the legs have occasionally been reported in patients who have been operated on for exophthalmic goiter and have had a recurrence of the toxic symptoms. Histologic examination of the tissue from these nodules reveals typical myxedematous changes. The following case is illustrative.

CASE 6—Mrs. P., aged 60, had typical exophthalmic goiter which developed at the age of 25. The treatment, as well as the result, varied greatly, but when she was 42 in 1917 her condition was such that a thyroidectomy was done. Microscopic examination of the gland showed a hyperplastic thyroid. For four years afterward the health was good but in 1921 there started a series of illnesses, and by January 1932 she had had six minor operations. In July 1932, when she was 57 she began having blisters and pustules on the soles of her feet, insteps and heels. These were very pruritic. A diagnosis of ringworm was made, and the treatment consisted of various topical applications, roentgen therapy and the use of antiseptic.

Fig. 2 (case 5)—The acini except a few are large. The lining cells are cuboid save in local areas where they are columnar. A few papillary masses project into the lumens and some of the colloid contains infiltrating monocytes. In one mass there are giant cells. There is no lymphocytic infiltration.

nervousness. It should be remembered that, next to mitral stenosis, thyroid intoxication is one of the usual causes for fibrillation. When the diastolic pressure is comparatively low, thus giving a wide pulse pressure and there is fibrillation without evidence of mitral stenosis, hyperthyroidism should be suspected. Little or no response to the administration of digitalis should arouse a strong suspicion of the presence of hyperthyroidism, and the use of iodine should be a great diagnostic help as well as a valuable therapeutic aid.

Toxic goiter, in elderly people, frequently simulates heart disease and many of the dependable diagnostic signs and symptoms are missing. If, however, there is hypertension with a wide pulse pressure and an increased pulse rate, iodine in small doses is worthy of a trial and often brings about surprisingly satisfactory results. It is, furthermore, almost axiomatic that dyspnea on exertion, tachycardia and palpitation in the absence of signs of heart failure are strongly suggestive of thyrotoxicosis.

The reactions of the skin to an increase of thyroxine in the blood, e. g., vasodilatation, flushing and sweating, are well known. While many cutaneous conditions are associated with thyroid deficiency, it is, I believe, rather

soaps. There was some improvement but the disease soon relapsed. At times it became so severe that the patient was confined to bed for as long as ten days or two weeks. She also became exceedingly nervous and was having trouble with her heart and by 1934 at the time of her examination by a dermatologist she had lost 40 pounds (18 Kg) in weight. The dermatologist's report was as follows: "There were a few nondescript scaly patches over the hands and slight pitting of a few of the finger-nails. The toe nails were very brittle, definitely cloudy and almost white on the distal half with keratotic debris beneath them. On the distal half of both soles there were pinhead to glass pinhead sized discrete pustules but no vesicles. Many pustules had involuted leaving brownish crusts. There were no lesions on the scalp, elbows or knees. Diagnosis: recalcitrant pustular eruption of the soles—a condition that is recognized as an entity."

The treatment instituted resulted in marked improvement but at no time did the condition entirely disappear. From this time on muscular weakness, nervousness, tremor and in fact all the symptoms of hyperthyroidism appeared and examination of the neck revealed two rounded nodules springing from the left lobe of the thyroid. The weight had gradually decreased. On Jan. 1, 1937, the recurrent hyperplastic thyroid tissue was removed from the left side of the trachea to which it had densely adhered. The pathologic report was "Fibrosis and chronic thyroiditis hyperplasia." The general response to the operation was unusual, but it is of interest that within seven days the lesion on the feet had cleared up entirely for the first time in nearly

five years and that up to the time of this writing there have been no signs of recurrence although no other treatment has been employed

CONCLUSIONS

What appear to be unusual aspects of hyperthyroidism depend not so much on the course of the disease itself as on unusual aspects of the aids to diagnosis. If the typical symptoms and signs are recognized and the normal metabolic rate is determined, little or no difficulty should be experienced in cases in which the rate is initially low. When the symptoms are associated with the autonomic imbalance group of nervous diseases, postinfluenzal parkinsonism and hypertensive cardiovascular disease, the use of iodine in combination with determinations of the basal metabolic rate will usually suffice to clear the diagnosis. The initial basal metabolic rate is frequently misleading and is responsible for many diagnostic errors. It is not the rate itself but rather the elevation above the patient's normal rate that is significant. Failure of the pulse rate to parallel the true basal metabolic rate should excite some doubt as to the presence of hyperthyroidism. A wide pulse pressure with hypertensive cardiovascular disease, particularly in elderly people and especially if tachycardia and auricular fibrillation are present should call attention to the thyroid. Failure of congestive heart disease to respond to medication with digitalis should arouse strong suspicion of an associated or causative thyrotoxicosis. The use of the iodine test should usually prove the presence or absence of toxic goiter.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED

FRANKLIN C. BING, Secretary

BLAIRS BEST FLOUR SELF RISING

Manufacturer—The Blair Milling Company, Atchison, Kan.

Description—A self-rising flour containing a patent flour of red winter wheat (bleached), salt, monocalcium phosphate and sodium bicarbonate.

Manufacture—The ingredients in formula proportions are mixed in a batch mixer and automatically packed in sacks.

Analysis—Moisture 13.0%, total solids 87.0%, ash 0.4%, fat (ether extract) 1.0%, protein (N×5.7) 9.3%, sodium chloride 2.0%, monocalcium phosphate 1.8%, sodium bicarbonate (NaHCO₃) 1.5%, crude fiber 0.2%, carbohydrates other than crude fiber (by difference) 76.1%.

Calories—35 per gram, 99 per ounce

STOKELY'S BRAND STRAINED APPLE SAUCE

Manufacturer—Stokely Brothers and Company, Inc., Indianapolis

Description—Canned strained apple sauce, slightly sweetened.

Manufacture—Selected apples are washed given a spray water bath under pressure, mechanically peeled and inspected. Canned apples are used out of season. A definite amount of sugar is added. The mixture is cooked and strained in an atmosphere of steam, heated to 98 C without exposure to air and filled into enamel-lined cans, which are then sealed and processed for thirty minutes at 100 C.

Analysis (submitted by manufacturer)—Moisture 79.2%, total solids 20.8%, ash, 0.8%, sodium chloride (NaCl) 0.6%, fat (ether extract) 0.8%, protein (N×6.25) 0.2%, crude fiber 1.0%,

carbohydrates other than crude fiber (by difference) 17.5%, reducing sugar as dextrose 13.4%, sucrose 3.2%, total acidity as malic acid 0.5%, pH 3.3

Calories—0.78 per gram, 22 per ounce

Vitamins—The natural vitamin content is retained in large measure in the manufacturing process by the use of equipment and procedure which exclude air, the hot mixture is exposed only to steam.

BAY SHORE BRAND SIEVED BEEF, SIEVED LAMB AND SIEVED LIVER

Manufacturer—H. B. Bashore Products, Inc., Los Angeles

Description—(1) Canned, cooked sieved beef

(2) Canned, cooked, sieved lamb

(3) Canned, cooked, sieved liver

Manufacture—(1 and 2) Coarsely ground lean beef or lamb, U. S. inspected and passed by the Department of Agriculture, is reground, passed through a one-sixteenth inch sieve, mixed with a small quantity of water, precooked for five minutes, packed in cans, sealed and heat processed.

(3) Calf liver U. S. inspected and passed by the Department of Agriculture, is seared in hot water, ground, passed through a one-sixteenth inch sieve, mixed with a small quantity of the water in which it was seared, precooked, packed in cans and heat processed.

Analysis (submitted by manufacturer)—

	Beef per cent	Liver per cent	Lamb per cent
Moisture	81.0	78.7	70.0
Total solids	19.0	21.3	30.0
Ash	0.9	1.0	1.0
Fat (ether extract)	1.1	3.5	7.8
Protein (N×6.25)	15.5	15.0	20.3
Crude fiber	0.1	0.04	0.1
Carbohydrates other than crude fiber (by difference)	1.4	1.8	0.8

Calories—Sieved beef, 0.8 per gram, 23 per ounce

Sieved lamb, 1.6 per gram, 45 per ounce

Sieved liver, 1.0 per gram, 28 per ounce

(1) I. G. A. BRAND CRYSTAL WHITE TABLE SYRUP

(2) I. G. A. BRAND GOLDEN TABLE SYRUP

Distributor—The Independent Grocers' Alliance Distributors, Inc., New York

Packer—Colonial Molasses Company, Brooklyn

Description—(1) A table syrup, corn syrup sweetened with granulated sugar syrup, flavored with vanilla.

(2) A table syrup, corn syrup flavored with refiners' syrup.

Manufacture—(1) Corn syrup and granulated sugar syrup are mixed, flavored with vanilla, heated to 70 C and sealed in tins.

(2) Corn syrup and refiners' syrup are mixed, heated to 70 C and sealed in tins.

Analysis (submitted by manufacturer)—

	(1) per cent	(2) per cent
Moisture	24.1	24.8
Total solid	75.9	75.2
Ash	0.3	1.6
Protein (N×6.25)	0.03	0.2
Reducing sugars as dextrose	29.3	31.5
Sucrose*	9.7	6.2
Dextrins (by difference)	36.57	36.1
Titrateable acidity as HCl	0.02	0.03
Sulfur dioxide (SO ₂)	0.002	0.004
pH (50% solution)	4.7	5.6

* Determined according to the A. O. A. C. method by invertase

Calories—3 per gram, 85 per ounce

SUFFOLK BRAND EVAPORATED MILK

Distributor—Suffolk Grocery Company, Inc., Boston

Packer—Page Milk Company, Merrill, Wis.

Description—A sterilized, unsweetened, evaporated milk, the same as Page Evaporated Milk (THE JOURNAL May 30, 1931, p. 1872).

SATURDAY, OCTOBER 9, 1937

DIET AND NEPHRITIS

Laboratory studies on the effects of dietary factors in nephritis have been stimulated by Masugi's¹ recent demonstration that chronic nephritis, closely resembling human Bright's disease, can be induced in laboratory animals by the intravenous injection of a properly selected organ-specific nephrotoxic serum. This work has apparently been confirmed by Smadel and Farr² at the Rockefeller Institute for Medical Research, who studied³ the effects of high protein diets on experimental chronic nephritis produced by this means in rats. These investigators studied the renal function, plasma proteins and hemoglobin of forty-eight young rats on routine laboratory diets. Severe nephritis was then produced in these rats by intravenous injection of the Masugi organ-specific antikidney serum. The animals were then divided into three groups, which were subsequently fed on three different isocaloric diets. Each diet contained 27 per cent fat (Crisco), 4 per cent salt mixture and adequate vitamins. In addition, diet 1 contained 64 per cent carbohydrate (Karo powder) plus 5 per cent protein (lactalbumin), diet 2 contained 51 per cent carbohydrate plus 18 per cent protein and diet 3 included 29 per cent carbohydrate plus 40 per cent protein.

The rate of growth of the rats on diet 1 was never as great as in rats on the intermediary or high protein diets. During the first month the course of the experimental nephritis was the same in all three dietary groups. Severe albuminuria and cylindruria appeared and persisted in all animals, anasarca was present for from a few days to several weeks, and plasma protein values were temporarily depressed. Neither blood urea nor urea clearance was significantly altered except in the single animal of each group which died during the first month from renal insufficiency.

During the second month nephritic symptoms diminished greatly or disappeared completely in all but two

of the animals on diet 1. Eight and a half months after injection of the nephrotoxic serum only one of the thirteen surviving rats on this low protein diet had urinary abnormalities. At this time five of these apparently fully recovered rats were changed to diet 3. During the ensuing two months, three of the five rats developed albuminuria with casts. Every animal fed on diet 3 from the time of injection of the nephrotoxic serum developed progressive nephritis. Only two of these animals were still alive at the end of eleven months. Both of these surviving rats were then in the terminal phase of Bright's disease. Rats fed from the time of the nephrotoxic serum injection on diet 2 had symptoms intermediate between those on diets 1 and 3.

The experiment ended at the end of eleven months. Microscopic studies of the tissues showed intense renal scarring in all rats fed on diet 3. Vascular lesions with degenerative changes were demonstrated in the hearts of most of these animals. Rats on diet 1 showed only a trace of renal damage, represented by old scarring.

From this investigation on experimental Bright's disease, Farr and Smadel conclude that in rats a "progressive chronic nephritis may follow a single toxic insult to the kidney" and that "the severity and course of the resulting nephritis is markedly influenced by diet." They recognize, however, that the experimental work was done solely on rats, with lactalbumin as the only protein variable. Whether or not other proteins are equally nephrotoxic when taken in excessive quantities has yet to be determined. The possibility of applying the Masugi technic to the production of chronic degenerative diseases of the central nervous system and other parenchymatous tissues also requires study.

PROGRESS IN INFLUENZA

In spite of the fortunate absence recently of pandemics of influenza such as the one that occurred in 1918, progress nevertheless is being made in the understanding of this disease. In December 1936, according to Stuart-Harris,¹ a rather extensive influenza epidemic afforded the opportunity for correlating the clinical events in man with the isolation of the influenza virus from patients. The principal question throughout this work was whether influenza virus infection in man constitutes a clinical entity or not. This question has been answered in the affirmative both by this author and by others. The great improvement in the ability to study the disease is derived largely from the fact that the influenza virus can produce in the ferret a short fever, with lassitude, nasal symptoms and nasal lesions, or an illness accompanied by the development of lung lesions varying in extent up to fatal pneumonic consolidation. The method of infecting ferrets, according to Andrews,² is relatively simple. The live virus from

a patient's unfiltered garglings are dropped from a pipet on a ferret's nose. When the virus is present in the inoculated material, the ferret shows fever and nasal symptoms after about forty-eight hours. Influenza in the ferret is spread by contact, and cross infections must thus be avoided by isolation.

As a rule, influenza virus will infect ferrets only when introduced directly into the respiratory tract. The pulmonary lesions, which can usually be produced only after serial passages in ferrets, are commonly bacteriologically sterile. The affected lungs are firm, moist and purplish red. Polymorphonuclear infiltration is not a feature, but patchy atelectasis is characteristic. The virus adapted to ferret lungs will infect mice, but Andrews reports varying success in attempts to adapt recently isolated human influenza strains to mice. In the latter animals, lesions only of the lungs are produced and the nasal passages are not affected. The evidence for the association of the virus with epidemics of human influenza seems convincing. The virus has been obtained from the garglings of patients with typical symptoms of influenza at times of widespread prevalence both in England and elsewhere. The serum of patients taken early in the infection has little or no power to neutralize the virus, but as early as the eighth day it will have acquired this power. A similar rise in antiviral titer does not occur in patients suffering from other respiratory diseases. An accident completed the cycle of evidence when in 1936 an infected ferret sneezed on Dr. Stuart-Harris and produced in him a typical attack of the disease.

Many other obscure facts have been uncovered by observing the disease in ferrets. Ferrets that have recovered from an attack of influenza develop potent neutralizing antibodies in their serums and are completely resistant to reinfection for about three months. After approximately six months this immunity has definitely decreased, and the animals can develop some symptoms when reinfected with high doses of the virus. The virus when given subcutaneously or by other routes, except the respiratory, is infectious only exceptionally but will produce some immunity, especially on repeated administration. It is exceedingly encouraging to note that these facts find a large measure of corroboration in the independent studies of Francis and his co-workers.³

The apparently satisfactory results of human vaccination by Francis and Magill⁴ encouraged Andrews to make a similar attempt. It was arranged through the cooperation of army authorities to vaccinate five groups, each of about 100 men, in different units, and to designate similar numbers as comparable controls. Unfortunately for the success of this attempt, an epidemic developed almost immediately and it was impossible to draw any definite conclusions other than

the fact that four persons vaccinated at least two weeks before exposure nevertheless developed clinical influenza, and from them the virus was obtained. It is thus evident that the method employed on that occasion is not 100 per cent effective.

A complicating factor has arisen from the recognition that not all strains of human influenza virus are serologically identical. Some of the differences are revealed by titrations of ferret serums, rabbit serums and cross immunity experiments. There is considerable antigenic overlap, and although the strains are more closely related to one another than to the swine influenza virus there are distinct differences. Clearly, this fact further confuses the epidemiologic and prophylactic studies, but it is to be hoped that it will not prove too great a stumbling block.

Current Comment

RELATION OF NICOTINIC ACID TO HUMAN PELLAGRA

Since the classic series of investigations on the relation of diet to pellagra begun in 1914 by Goldberger and his collaborators of the United States Public Health Service, investigators have been attempting to concentrate and purify the dietary factor concerned in the prevention of human pellagra. The progress of these studies was greatly facilitated by the work of Chittenden and Underhill.¹ These investigators, using diets similar to those associated with human pellagra, were able to produce experimental blacktongue in dogs. They demonstrated that this disease was similar to, if not identical with, human pellagra. Conditions were thus provided for assaying experimentally the various fractions obtained during efforts to concentrate and identify the antipellagra dietary factor. Highly active concentrates have been prepared by a number of investigators. Recently, workers at the University of Wisconsin, in a preliminary note,² have reported the isolation, in crystalline form, of nicotinic acid amide from active liver concentrates. The crystalline compound was found to be highly active in the cure of experimentally produced blacktongue of dogs. Furthermore, nicotinic acid, prepared from the amide, was also therapeutically effective, as was a synthetic preparation of pure nicotinic acid. A single dose of 30 mg. of nicotinic acid gave a striking response in a dog suffering from blacktongue. The appetite improved immediately, the animal showed a growth response similar to that observed on the original liver extract, the diarrhea disappeared, and on further additions of the nicotinic acid growth continued without interruption. Similar responses are reported to have been obtained in four dogs. One dog on the basal, blacktongue-producing ration, was fed 100 mg. of nicotinic acid each week for three weeks with no indication of recurring symptoms and the dog appeared normal in every way. These striking results with nicotinic acid recall the experiments of Funk in 1911,

in the early period of vitamin investigation. While attempting to purify the dietary factor effective in the cure of human beriberi, Funk asserted that he had isolated the active substance in an approximately pure form.³ This material was believed to be a combination of nicotinic acid and a pyrimidine. It is interesting that Funk, a pioneer investigator in the field of vitamins, who introduced the name "beriberi vitamine," demonstrated that nicotinic acid is a constituent of the naturally occurring vitamin B complex, even though he had apparently assigned the wrong physiologic function to his compound. The phenomenal response of canine blacktongue to nicotinic acid and to nicotinic acid amide will stimulate careful investigation to determine their possible clinical value in cases of human pellagra.

THE VITAMIN CONTENT OF FOODS

A brief compendium of new information about the chemistry of the vitamins, units of measurement and tables of vitamin content of common foods has just been published by the United States Department of Agriculture.¹ This upholds the enviable reputation of the department in the laborious task of compiling data on the composition of foods. As long ago as 1895 W. O. Atwater and his associates collected data on the composition of hundreds of American food materials. This list was revised and amplified, the latest revision appearing in 1906, and today Bulletin 28 by Atwater and Bryant is known far and wide as an authoritative catalogue of the chemical composition of foods in terms of protein, fat, total carbohydrate, fiber, ash, water and fuel value. More recent workers, particularly in the Bureau of Home Economics, have collected and tabulated data covering the proximate composition and iron content of fresh fruits and vegetables. In 1929 Sybil L. Smith in the Office of Experiment Stations published a report on the vitamins in food materials but had to list most of the data in terms of plus and minus signs. In the present publication Daniel and Munsell have been able to obtain from reports in the literature quantitative information in terms of units of vitamins per hundred grams of food. The vitamin A, B₁, C, D and G content of foods is conveniently summarized in tables together with the references to the investigators who originally published the data. The bibliography lists nearly 800 citations of papers in technical and medical literature. Practically every conceivable form of food seems to have been the subject of investigation. It is curious to note, however, that the tables do not include white bread and whole wheat bread, although reports are available regarding the vitamin B₁ content of these common foods. The authors have presented a brief introductory summary of the current information on the chemical structure of the vitamins, definitions of units and discussions of methods of assay. As they have pointed out, the tables will undoubtedly need to be revised in the future so as to record the data in terms of the preferred international units, which

are based on definite standard substances, whereas Sherman units, which have been widely used and in which system most of the figures in the present work are recorded, are based on the growth response of animals. In the discussion of factors for converting Sherman or other units into approximate international units, the authors have neglected to include a common factor for converting Steenbock units of vitamin D into the international system. Most investigators have found that one Steenbock unit of vitamin D equals about 27 international units, although it is recognized that this value may vary in different laboratories. The book includes a separate table of the vitamin C (ascorbic acid) content of foods as determined by chemical titration methods and by assay methods with guinea pigs. A third table provides a brief digest of what the authors consider to be the best average values for the expected vitamin content of some 200 common foods. So many advances have been made in our knowledge of the vitamins that it is difficult even for experts to keep up with the literature. This practical handbook is indispensable for those seeking recent, authoritative information about the value of foods as sources of the vitamins.

AIR TRAFFIC AND THE SPREAD OF YELLOW FEVER

New means of communication, such as automobile roads, airplane services and new railroads, introduce new problems in the control of communicable disease. The Pan American Sanitary Bureau has been studying jungle yellow fever with the view of limiting the disease to those South American countries in which it has been proved to exist. The bureau, keeping abreast with the rapid expansion of the air travel by the lines of the Pan American Airway System, has made arrangements to prevent the international spread of yellow fever by air traffic.¹ Under the terms of the agreement, all the flying personnel of the company will be vaccinated against yellow fever. Furthermore, each passenger embarking in a Pan American Airways plane at any point north of 30 degrees south latitude will be required to fill out a form designated as "Certificate of Origin of Passenger." The questions included in this form deal chiefly with an accounting of the passenger's location for the six days preceding embarkation at the airport. This period, taken together with the time consumed on the voyage, gives a fairly wide margin of safety. In instances in which passengers have come from actually infected localities and the six day period of incubation since the last possible exposure has not been completed on arrival at destination, the passengers, according to the discretion of the quarantine officer, may be placed in open surveillance, observation or detention, as may be deemed safest and most expedient. Finally, as an additional precaution, airplanes will be fumigated during the night, when not in use. This recognition of the dangers attending the facilitation of the spread of disease by air traffic, and the noteworthy measures taken for its prevention, constitute an important chapter in epidemiology.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES NEW HOSPITALS EDUCATION AND PUBLIC HEALTH)

ALABAMA

Courses in Venereal Disease Control—With social security funds, the state department of health is financing a refresher course at the U S Public Health Service Venereal Disease Clinic at Hot Springs, Ark. Physicians are selected by their respective county medical societies. Only one physician is chosen from each county. The period of study is one month and the stipend is \$200 for married men and \$150 for single men, plus transportation. One course began September 1.

Personal—Dr Thomas M Towns, formerly of Clarence, has been appointed health officer of Blount County succeeding Dr Samuel D Sturkie, Oneonta, who accepted a similar position in Calhoun County.—Dr William D Burkhalter formerly of Rockford has resigned as health officer of Coosa County to become assistant director of the division of venereal disease control of the bureau of preventable diseases state department of health. He will be succeeded by Dr William H Goff, Glasgow. Both appointments were effective September 15.

ARIZONA

Dr Dunshee in Charge of Local Health Administration—Dr Jay Dee Dunshee, until recently director of public health of Idaho, has been appointed director of local health administration of Arizona according to *Arizona Public Health News*. He succeeds Dr Alvin N Cram Phoenix. Dr Dunshee formerly served among other positions as director of child welfare of Los Angeles, health officer of Pasadena and director of the state health department of California.

ARKANSAS

Meeting Dedicated to Physicians in Practice Fifty Years—The sixteenth session of the Fort Smith Clinical Society in Fort Smith, October 12, will be dedicated to those physicians in northwestern Arkansas who have been in practice for fifty years. Clinics at the Sparks Memorial Hospital will make up the program in the morning. In the afternoon Dr Laurence M Randall, Rochester, Minn. will discuss 'The Treatment of Disturbances of Genital Physiology Among Women' and Dr L A Day, Rochester, 'The Irritable Heart Syndrome and Its Accompaniments.'

CALIFORNIA

Fatal Case of Human Plague—According to *Public Health Reports* Dr Walter M Dickie, Berkeley, director of public health of California, August 30, reported a fatal case of human plague in Fresno.

Society News—Dr Albert H Rowe, Oakland, addressed the Hollywood Academy of Medicine in Hollywood September 16, on "Clinical Aspects of Chronic Allergy"—At a meeting of the Alameda County Medical Association in Oakland, September 20, the speakers were, among others Drs Lloyd E Kindall on "Traumatized Kidney and Hobart Rogers, "Protamine Insulin Shock."

Annual Secretaries' Conference—The annual joint conference of county secretaries, standing committees and officers and councilors of the California Medical Association was held in San Francisco, October 2, at the Sir Francis Drake Hotel. Dr Irvin Abell, Louisville, Ky, President-Elect American Medical Association, spoke at the afternoon session. The speakers on the program included

Dr Junius B Harris Sacramento Public Policy and Legislation
Dr Morton R Gibbons Sr San Francisco Industrial Practice
Dr George G Reinle Oakland Medical Defense
Dr Howard Morrow San Francisco Venereal Disease

COLORADO

State Medical Election—Next Meeting in Estes Park—Dr Leo W Bortree, Colorado Springs, was chosen president-elect of the Colorado State Medical Society at the annual meeting in Colorado Springs, Dr William T H Baker Pueblo, was installed as president. The revised constitution for the society, proposed in 1936 and tentatively approved at

that time by the house of delegates, was adopted. An amendment removing from the by-laws the amount of annual dues and instead giving the board of trustees power annually to fix the state dues was adopted. Approval was also given to the expansion of *Colorado Medicine* into the *Rocky Mountain Medical Journal* beginning with the January issue. The next annual meeting of the society will be held in Estes Park, with the Denver delegation acting as host in view of the fact that the profession in Estes Park is small in number and entertained as recently as three years ago.

DISTRICT OF COLUMBIA

University News—Dr Leland O W Moore, formerly of Honolulu, Hawaii, has been appointed professor of military science and tactics at George Washington University School of Medicine, Washington. The annual faculty address at the opening session of the medical school was delivered September 22 by Dr Francis R Hagner, executive officer of the department of urology, on "The Early History of the George Washington University School of Medicine."

Hospital News—The Medical Society of St Elizabeth's Hospital, Washington, was recently organized by a number of present and former members of the medical staff of the hospital. It is planned as an alumni society of the hospital to include physicians now serving, or having served in the past, at the hospital. In general it will sponsor and support efforts tending to promote the best interests of the institution, and its program will include a plan of guided psychiatric research at the hospital. Communications from former staff members, including medical officers in the military services who have been assigned to the hospital, are invited and should be addressed to the secretary Dr Jay L Hoffman, St Elizabeth's Hospital. Other officers are Drs Addison M Duval, president, and Joseph L Gilbert, vice president.

GEORGIA

Changes in Health Officers—Dr Fritz A Brink, recently of Blackshear has been appointed director of the newly created department of health in Clinch County, with headquarters in Homerville.—Dr George Marvin Anderson, Atlanta, has been appointed commissioner of health of Calhoun County effective August 15.—Dr Robert Frank Cary Dawson, health officer of Terrell County since January 1936, has resigned, effective October 1.

Surgical Conference—The Georgia section of the South-eastern Surgical Congress held its fourth annual clinical conference at Canton, September 22. Speakers included

Dr Henry W Birdsong Athens Use of Beef Bone in the Open Treatment of Fractures
Dr Fred F Rudder Fort McPherson Inguinal Hernia
Dr Enoch Callaway LaGrange Breast Tumors
Dr Stephen T Brown Atlanta Use of Sulfanilamide in Infections of the Urinary Tract
Dr George A Taylor Augusta president, state medical association Medical Societies
Dr Benjamin Russell Burke Atlanta Sinusitis Acute and Chronic
Dr Charles E Rushin Atlanta Acute Appendicitis
Dr George F Eubanks Atlanta Carcinoma of the Descending Colon
Dr Warren S Dorrough Atlanta Diastasis of Abdominal Incision

Dr Benjamin T Beasley, Atlanta, secretary of the South-eastern Surgical Congress, was also on the program.

ILLINOIS

Society News—Dr Joseph M Keller, St Louis, discussed "Disease of the Eye" before the Madison County Medical Society at its meeting in Alton, October 1.—Dr Joseph J Eller New York will address the Peoria City Medical Society October 16 on 'The Latest Methods of Treatment of Skin Conditions.' At a meeting of the society, October 5 Dr Laurence H Mayers, assistant professor of medicine, Northwestern University Medical School, Chicago, discussed "Treatment of Arthritis."

Chicago

The Belfield Lecture—Dr Dalton K Rose, assistant professor of clinical genito-urinary surgery, Washington University School of Medicine, St Louis will deliver the ninth annual William T Belfield Lecture of the Chicago Urological Society, October 21, at the Palmer House. His subject will be "Neurologic Anatomy and Physiology of the Bladder and Its Clinical Application in Urology." A dinner will be held preceding the meeting to honor Dr Rose.

Lectures on Psychoanalysis—Dr Franz G Alexander, director, Institute for Psychoanalysis, will conduct an introductory course of lectures on psychoanalysis during the first

and second quarters of the institute, beginning October 27. The course will include the following subjects:

Historical Development of the Main Concepts of Psychoanalysis
Concept of the Unconscious
The Fundamentals of Psychic Dynamics
Theory of Instincts
Theory of Dreams
Development of the Personality
General Concepts of the Structure of Neuroses and Psychoses
Principles of the Psychoanalytic Technique
Application of Psychoanalysis to Other Sciences

Beginning October 23, Dr. Leon J. Saul will present a review of psychoanalytic writings on sociological subjects. Conferences and seminars will make up the regular program for members of the Chicago Psychoanalytic Society and candidates of the institute only, with Drs. Alexander, Thomas M. French and Therese Benedek as the lecturers.

INDIANA

Deadline for Indiana Cities to Stop Lake Pollution—It was announced September 16 that Jan. 1, 1939, has been set as the deadline when the cities of Gary, Hammond, Whiting and East Chicago must have abated their contribution to the pollution of the streams in their vicinity and of Lake Michigan. The cities have the right of appeal before the state board of health. The four cities were ordered Dec. 10, 1927, to construct sewage treatment works, but little, if any, action has been made toward compliance with those orders, it was reported. The state's complaints against Gary and Hammond charge contamination of the Little Calumet River, the Grand Calumet River, the Indiana Harbor ship canal and Lake Michigan. Whiting is charged with polluting Lake Michigan, while East Chicago is accused of contaminating the lake, the ship canal and the Grand Calumet River.

KANSAS

Personal—Dr. Emery Trekel, Wellington, has been appointed health officer of Sumner County.—Dr. Marlin W. Carlson, Ellinwood, has been named health officer of Barton County.

Society News—The Pottawattamie County Medical Society will be addressed in Council Bluffs October 25 by Drs. Logan Clendening, Kansas City, Mo., on "Medical Shrines at Home and Abroad", William E. Ash, Council Bluffs, "Hypoglycemia in the Treatment of Schizophrenia," and Gerald V. Caughlan, Council Bluffs, on "Present Status of Prostatic Resection." The society was addressed September 20 by Dr. Karl A. Meyer, Chicago, among others, on "Surgical Treatment in Regional Enteritis."—The Wyandotte County Medical Society was addressed in Wyandotte, September 7, by Drs. Maurice A. Walker on "Washing Machine Injuries" and Clifford J. Mullen, Kansas City, "External Diseases of the Eye."—The Barber County Medical Society was recently organized at a meeting in Medicine Lodge. Dr. Joseph D. Warrick, Kiowa, was chosen president, and Dr. Kenneth R. Grigsby, Medicine Lodge, secretary.

MAINE

Annual Clinical Session at Portland, October 21-22—The annual clinical session of the Maine Medical Association will be held at Portland, October 21-22, at the Maine General, Children's and St. Barnabas hospitals, and at the Maine Eye and Ear Infirmary. The Cumberland Medical Society will act as host. Dr. Milton C. Winternitz, Anthony N. Brady, professor of pathology, Yale University School of Medicine, New Haven, will address the dinner session Thursday evening at the Eastland Hotel. His subject will be "The Pathology of Vascular Diseases." Special meetings during the session will include a luncheon meeting of the council of the association, October 21 and one of the county secretaries, October 22. A meeting of the advisory board of the Maine division of the Women's Field Army for the Control of Cancer is planned for Friday morning, October 22.

MARYLAND

Baltimore Opens Third Health District—The Baltimore Health Department opened the Southeastern Health District, August 16, the third of the eight health districts into which the city is being divided. With headquarters in a former school building at 901 South Kenwood Avenue, the new unit includes all of the first, second and third wards and that portion of the twenty-sixth ward south of Federal Street, embracing a population of about 100,000 persons. Dr. William H. F. Warthen, assistant commissioner of health, will have direct charge of the new health district for the next six months and will be assisted by Dr. John A. Skladowsky, the full time

district health officer. Like the Eastern Health District just to its north, the new unit will have as a cooperating agency the Babies' Milk Fund Association, which will conduct child hygiene clinics in the district building as an adjunct to the antepartum clinics of the health department. Other services for vaccination and diphtheria prevention will also be conducted for families unable to afford private medical care, according to *Baltimore Health News*.

MASSACHUSETTS

Personal—Dr. Arthur H. Davison, Boston, has been made medical director of the Boston Mutual Life Insurance Company. He has been associate director for several years.—Dr. Gaylord P. Coon, Stockbridge, has been appointed chief medical officer of the Boston Psychopathic Hospital, succeeding Dr. Jackson M. Thomas, who resigned to become associate professor of psychiatry at the University of Louisville School of Medicine, Louisville, Ky.

New Building for Tufts Medical School—Plans formulated by the alumni council of Tufts Medical Association for the erection of a new medical school building at the New England Medical Center, Boston, were approved by the trustees at a meeting, September 8, according to the *Boston Sun*. A fund of \$2,000,000 will be raised by public appeal among the alumni of the school and the people of New England, to be used for the building and endowment of various professorships and for the creation of a much needed surgical unit at the Boston Dispensary, it was stated.

MINNESOTA

Society News—Dr. John F. Norman, Crookston, was chosen president of the Northern Minnesota Medical Association at its meeting in Virginia, August 27-28. Dr. Owen W. Parker, Ely, was named vice president and Dr. Clarence Jacobson, Chisholm, secretary-treasurer. The next annual meeting will be held in Crookston.—Dr. Albert E. Meinert, Winona, was elected president of the Southern Minnesota Medical Association at a meeting, August 11. Other officers are Drs. Walter A. Fansler, Minneapolis, and Albert Fritzsche, New Ulm, vice president, and Dr. Nelson W. Barker, Rochester, secretary.—The Hennepin County Medical Society and the Minnesota Pathological Society will hold a joint meeting November 1. Dr. Arnold S. Jackson, Madison, Wis., will discuss "Errors in the Diagnosis and Treatment of Hyperthyroidism," and Dr. Eleonora T. Bell, Minneapolis, the pathologic aspects.

NEVADA

Plague Infection in Ormsby County—Under date of August 30 it was reported that plague had been demonstrated in a lot of 134 fleas collected from three ground squirrels (*Citellus beecheyi*) shot thirteen miles west of Carson City on August 20, according to *Public Health Reports*.

NEW JERSEY

Society News—The New Jersey Tuberculosis League will hold its annual meeting in New Brunswick, October 22.—Dr. Earl W. Fuller, Greystone Park, addressed the Bergen County Medical Society, Englewood, September 14, on "Mental Hygiene and the General Practitioner."

Dr. Northrop to Receive Chandler Medal—John Howard Northrop, Ph.D., member of the Rockefeller Institute for Medical Research stationed at the Princeton branch, is to receive the 1937 Chandler Medal awarded by Columbia University, New York, in recognition of his "fundamental discoveries concerning bacteria, the constitution of proteins and the chemistry of digestion." The presentation will be made October 27 during a month's celebration by the university of the one hundredth anniversary of the birth of Charles Frederick Chandler, called the "father of industrial chemistry" and New York's first public health chemist. Dr. Northrop will deliver an address on "The Chemical Nature and Mode of Formation of Pepsin, Trypsin and Bacteriophage."

NEW YORK

Mental Hygiene Commissioner Appointed—Dr. William J. Tiffany, superintendent of the Pilgrim State Hospital, Brentwood, has been appointed state commissioner of mental hygiene to succeed Dr. Frederick W. Parsons, who retired October 1. Dr. Tiffany, who is 55 years old, entered the state hospital service in 1906 and served on the staffs of the Binghamton State Hospital, Manhattan State Hospital and the Kings Park State Hospital, of which he was made superintendent in 1926.

In 1931 he was appointed head of the Pilgrim State Hospital. He was graduated from Columbia University College of Physicians and Surgeons, New York.

District Meetings—At the annual meeting of the Third District Branch of the Medical Society of the State of New York in Kingston, September 30, the speakers included Drs. Milton C. Wintermiz, New Haven, Conn., on "Pathology of Vascular Disease," Howard F. Root, Boston, and Stephen H. Curtis, Troy, "Dialogue on the Use of Protamine Zinc Insulin and Other Diabetic Problems." Dr. Charles H. Goodrich, Brooklyn, president of the state society, spoke on preventive medicine. Guest speakers at the annual meeting of the Fourth District Branch at Glens Falls, October 1-2, were Drs. Benjamin W. Carey Jr. and Paul Dudley White, Boston, on "The Use of Sulfanilamide in the Treatment of Infections of Childhood" and "The Prevention of Heart Disease" respectively. The program of the Sixth District Branch meeting in Oswego, September 21, included addresses by Drs. Irving S. Wright, New York, on "Newer Aspects of the Treatment of Peripheral Vascular Diseases," Anton W. Sohrweide Jr., Syracuse, "Diagnosis and Management of Cutaneous Cancer," and John S. Lawrence, Rochester, N. Y., "Diagnosis and Practical Measures in the Treatment of Anemia." The annual joint meeting of the Seventh District Branch of the state medical and dental societies was held in Geneva, September 22. At the morning session addresses were made by Drs. David A. Haller, Rochester, on obesity, Edward S. Rogers, Albany, pneumonia control, and Burton T. Simpson, Buffalo, etiology of cancer. In the afternoon Dr. Charles H. Goodrich, Brooklyn, president of the state medical society, Edwin I. Harrington, DDS, Watertown, president of the state dental society, and Dr. Theodor Blum, New York, discussed medicodental cooperation.

New York City

Personal—Dr. Edward H. Linnehan, Brooklyn, has been appointed director of the medical service of the United States steamship lines, which is to be expanded it is said. Dr. Simon Flexner, director emeritus of the Rockefeller Institute for Medical Research, sailed for England September 25 to spend the academic year as Eastman visiting professor at the University of Oxford. The professorship was founded by the late George Eastman of Rochester.

Society News—The Medical Society of the County of Nassau was addressed in Mineola, L. I., September 28 by Drs. Russell L. Cecil, New York, on "The Serum Treatment of Pneumonia," Edward S. Rogers, Albany, "The State Campaign Against Pneumonia," and Theodore J. Curphey, New York, "The Bacteriology of Pneumonia and the Modern Method of Typing." Dr. Theodore Neustaedter, New York, addressed the Medical Society of the County of Queens, October 1, on "Diagnosis and Treatment of Uterine Bleeding of Endocrine Origin."

OHIO

Outbreak of Typhoid with Three Deaths—The use of raw milk was responsible for a recent outbreak of typhoid in Portsmouth according to *Public Health Reports*. Since the middle of June and up to September 3 there had been sixty-eight cases in the city and twenty in Scioto County, outside the city, with three deaths. Investigation showed that 61 per cent of the cases occurred in persons supplied by a raw milk dairy which distributed only 1 per cent of the milk used in the city.

Lectures on Pathology—Dr. Herbert S. Reichle, Cleveland, is giving a series of lectures on pathology under the auspices of the Mahoning County Medical Society in Youngstown. The first was presented October 6 and the series will follow on succeeding Wednesdays until November 24. It includes three lectures on neoplasms, three on the degenerative, defensive and regenerative processes in pathology, one on the law of obstruction in pathology, and one on the phenomenon of foreign protein sensitivity.

OREGON

State Medical Meeting at Salem, October 21-23—The sixty-third annual session of the Oregon State Medical Society will be held at the Hotel Marion, Salem, October 21-23, under the presidency of Dr. Charles E. Sears, Portland. Guest speakers will include Drs. Lester R. Dragstedt, Chicago, on "Pathogenesis and Surgical Treatment of Duodenal Ulcer" and "Pathogenesis and Surgical Treatment of Acute Intestinal Obstruction," Fuller Albright, Boston, "Hyperparathyroidism," and "Medical Aspects of the Treatment of Renal Stones," and William Waldo Bauer, Chicago, director, bureau of health and

public instruction, American Medical Association, who will address the annual banquet Friday evening on "Teaching the Public About Health." Included among Oregon physicians on the program will be

Dr. Arthur C. Jones, Portland, "Technic and Dangers of Short Wave Radiotherapy,"
Dr. John E. Raaf, Portland, "Surgery of the Sympathetic Nervous System for Essential Hypertension,"
Dr. Roy C. McDaniel, Portland, "The Injection Treatment of Hernia: What Are Its Complications and the Destiny of the Sac?"
Dr. Vern W. Miller, Salem, "Aplastic Anemia Due to Sensitivity to Benzamine Derivatives,"
Dr. Matthew C. Riddle, Portland, "Factors Affecting Blood Regeneration,"
Dr. Adolph Weinzirl, Portland, "Public Health Aspects of Rabies with Particular Respect to Its Control,"
Dr. Charles P. Wilson, Portland, "The Tachycardias: Their Recognition and Treatment."

A symposium on public health activities authorized by the social security act will be held Thursday night by the following members of the state board of health: Dr. George D. Carlyle Thompson, director of maternal health, Floyd H. DeCamp, DDS, director of oral health, Dr. August E. Bostrom, director of county health units, and Dr. Frederick D. Stricker, state health officer.

PENNSYLVANIA

Society News—Dr. Roy R. Snowden, Pittsburgh, addressed the Beaver County Medical Society, September 9, at the Beaver County Sanatorium, Monaca, on nephritis. Dr. Harold W. Jones, Philadelphia, addressed the Lehigh County Medical Society, Allentown, September 14, on blood dyscrasias. At the annual meeting of the Association of Surgeons of the Pennsylvania Railroad at the Hotel William Penn, Pittsburgh, October 1-2, out of state speakers included Drs. Ralph G. Carothers, Cincinnati, on "Treatment of Fractures of Neck of Femur by Internal Fixation," Fred H. Albee, New York, "Surgical Reconstruction of the Lever at the Top of the Femur and Its Importance," Frank Warner, Columbus, Ohio, "The Hospitals and Diseases of South America," and Benjamin I. Golden, Elkins, W. Va., "Hernia Technic." Dr. Frederick A. Bothe, Philadelphia, addressed the Northampton County Medical Society, Easton, September 24, on "Surgery in the Diabetic Patient." Dr. I. Hope Alexander, Pittsburgh, discussed "Public Health" before the McKeesport Academy of Medicine at its meeting in McKeesport, September 27. Dr. William H. Stoner, Tuckahoe, N. Y., addressed the Lycoming County Medical Society, September 10, on "Recent Therapeutic Advances."

TENNESSEE

Personal—A group representing medicine and dentistry in Nashville attended a dinner at the invitation of Dr. John J. Mullaney, president of Meharry Medical College, in honor of Dr. Edward Lewis Turner, head of the department of internal medicine, September 2. Dr. Turner was formerly professor of internal medicine at the American University in Beirut, Syria.

TEXAS

Personal—Evan W. McChesney, Ph.D., associate professor of biologic chemistry at the University of North Carolina School of Medicine, Chapel Hill, has been appointed to the faculty of the Baylor University School of Medicine, Dallas. Dr. Clarence Burke Brewster, Fort Worth, has resigned as health officer of Tarrant County to become school physician for Fort Worth. Dr. Charles W. Butler Jr., Crockett, has been appointed a member of the state prison board. Dr. William M. Dickens, Greenville, has been appointed to the state board of health to succeed the late Dr. Samuel A. Woodward, Fort Worth.

Society News—The Texas Association of Gynecologists and Obstetricians will meet jointly with the Central Association of Obstetricians and Gynecologists at the annual meeting of the latter in Dallas, October 14-16. The Texas group will have as its guest Dr. John A. Kolmer, Philadelphia, who will speak on "Syphilis Complicating Pregnancy" and "Treatment of Septicemia with Reference to Sulfanilamide." Dr. Charles M. Campbell, Boston, will be the guest of the Central association. His subject will be "Personal and Environmental Factors in Obstetrical and Gynecological Practice." Drs. Julius McIver and Samuel A. Shelburne, Dallas, addressed the Gray-Wheeler Counties Medical Society, Wheeler, August 17, on "Mechanism of Labor" and "The Use of Digitalis in Certain Diuretics and the Management of Cardiac Decompensation" respectively. Dr. Ozro T. Woods, Dallas, addressed the Angelina County Medical Society, Lufkin, September 9, on "Treatment of Tumors of the Breast."

WISCONSIN

Society News—At a meeting of the Eleventh Councilor District Medical Society in Mellen, August 7, Dr Stephen E Gavin, Fond du Lac, then president of the State Medical Society of Wisconsin, made an address on "Legislation Affecting the Practice of Medicine in Wisconsin." On the scientific program were Drs John R Goodfellow, Superior, on "Rest in Psychopathic Cases" and James C Sargent, Milwaukee, "Transurethral Resection A Milestone in Surgery of the Bladder and Prostate"—Dr Byrl R Kirklin, Rochester, Minn, addressed the Rock County Medical Society, Beloit, recently on "Roentgenologic Examination of the Alimentary Tract and Indications Therefor."

Study of Accident Prevention—A special survey designed to achieve more effective methods of accident prevention is now being carried on in Wisconsin under the direction of Dr Carl J Kornreich, special federal agent, department of vital statistics, bureau of the census, Washington, D C, according to the bulletin of the state board of health. Recent accident fatalities will be studied and more complete information than is contained in the death certificates on file at the state bureau of vital statistics will be gathered. A similar study was conducted in Baltimore, it was stated, but Maryland's rural population was considered too small to complete a typical state picture. Special attention is being given to automobile and home accidents in the hope of developing more successful prevention programs, but all types of accidents will figure in the survey, it was reported.

GENERAL

New Bulletin on Radiology—The Bulletin of the Inter-Society Committee for Radiology, the recently organized representative body for the American Roentgen Ray Society, Radiological Society of North America, American Radium Society and the American College of Radiology, made its first appearance with the August issue.

Annual Meeting of Dietetic Association—The twentieth annual meeting of the American Dietetic Association will be held in Richmond, Va, October 17-23. The preliminary program announces a symposium on pellagra with the following speakers: Dr William H Sebrell Jr, U S Public Health Service, William J Dann, Ph D, and Dr David T Smith, Durham, N C, and Dr Tom D Spies, Cincinnati. Among other speakers will be Elmer V McCollum, Ph D, Baltimore, on "Recent Developments in the Field of Nutrition", Dr James S McLester, Birmingham, Ala, "The More Abundant Diet," and Dr Warren T Vaughan, Richmond, "Newer Developments in the Treatment of Food Allergy."

American Academy of Dermatology and Syphilology—A special committee appointed at the meeting of the Section on Dermatology and Syphilology of the American Medical Association in Atlantic City in June held a meeting in Chicago September 10 and voted to organize the American Academy of Dermatology and Syphilology. The original committee of seven was enlarged to seventeen members, as follows: Drs Harold N Cole, Cleveland, Oliver S Ormsby and William A Pusey, Chicago, Clarence Guy Lane, Boston, Howard Morrow, San Francisco, Paul A O'Leary, Rochester, Minn, Elmore B Tauber, Cincinnati, Frederick D Weidman, Philadelphia, Udo J Wile, Ann Arbor, Mich, George M MacKee, Howard Fox and Fred Wise, New York, Harry R Foerster, Milwaukee, Earl D Osborne, Buffalo, Harry J Templeton, Oakland, Calif, Martin T Van Studdiford, New Orleans, and Richard S Weiss, St Louis.

Epidemiology of Venereal Lymphogranuloma—Dr Sven Hellerstrom, S t Goran's sjukhus, Stockholm (Sweden), is undertaking a world wide study of the incidence of venereal lymphogranuloma. He is anxious to receive from individual physicians statements as to the number of cases of venereal lymphogranuloma which they have seen personally, including only those in whom Frei's intracutaneous reaction has been carried out. It is wished also to show a record of the distribution of the cases by months during the year, sex and age incidence, the duration of the period of incubation, classification of various forms of the disease, a record of extragenital primary disorders, a statement as to the part of the world in which the patient became infected, and also a note as to cases complicating other venereal diseases, mortality records, and also instances of esthiomene (chronic ulcer of the vulva and anorectal syphiloma) due to venereal lymphogranuloma.

Society News—Dr Harvey Bartle Philadelphia, was elected president of the American Association of Railway Surgeons at its annual meeting in Chicago September 22. Drs

James Frank Dinnen, Cleveland, John G Hayden, Kansas City, Mo, and Willis C Campbell, Memphis, Tenn, were chosen vice presidents and Dr Daniel B Moss, Chicago, was reelected secretary.—Dr George Harvey Agnew, Toronto, was chosen president-elect of the American Hospital Association at the annual meeting in Atlantic City, September 13-17. Mr Robert E Neff, administrator of the University of Iowa Hospital Iowa City, was installed as president. Dr Robin C Buerki, Madison, Wis, was made president of the American College of Hospital Administrators, which met at the same time.—The National Society for the Prevention of Blindness held its annual meeting October 6 at the Hotel Pennsylvania, New York. Dr William F Snow, New York, managing director American Social Hygiene Association, delivered an address on "Saving Sight Through Public Action".—Dr Ladislaus J Dancelski, Gary, was elected president of the Polish Medical and Dental Association of America at its annual convention in Boston, August 26-28.—The annual National Hearing Week, sponsored by the American Society for the Hard of Hearing, will be observed October 24-30.

Annual Report of Rockefeller Foundation—According to the annual report of the Rockefeller Foundation, \$1,623,750 was expended in 1936 for projects in the medical sciences. Of this sum \$702,050 was disbursed for research in psychiatry and allied subjects, \$112,000 for the teaching of preventive medicine and public health, \$130,000 for fellowships, \$110,000 for small grants in aid, and \$569,700 to projects of the former program, principally to the China Medical Board Inc, for maintenance of the Peiping Union Medical College. In donating \$11,300,000 during 1936 in connection with its world wide program the foundation cooperated financially with 130 agencies, including forty-one local and national governments, forty-four educational institutions, two libraries and twenty-three councils, associations, societies and commissions, most of them national or international in scope. The foundation's activities were carried on in fifty-three foreign countries, with the disbursements in this field totaling \$3,621,000 or about one third of the total expenditures of the year. The work of the International Health Division of the Rockefeller Foundation in 1936 was conducted on a budget of \$2,100,000 in thirty states of the United States and in forty-one foreign countries. The major portion of the budget went to laboratory and field services and to the control and investigation of specific diseases. About one fourth of the amount was devoted to public health education and to the aid of state and local governments in setting up model health centers and demonstrations.

The aid given in psychiatry has been of various types covering different avenues of approach to the general problem. In 1936 appropriations were made for the development of a number of psychiatric clinics and university departments of psychiatry or neurology, for the general diffusion of information on psychiatry and the improvement of psychiatry and neurology, studies in child psychiatry and delinquency, for studies of viruses affecting the nervous system especially the virus of poliomyelitis, for studies of the role played by inheritance in the causation of mental disease and defect, and for studies of conditioned reflexes and the interrelation of emotional and mental states with physical diseases and disabilities.

Seventy-seven fellowships in the medical sciences were administered directly by the foundation during 1936, twenty-six of these were granted from General Education Board funds under a joint program. The fellowships of the Rockefeller Foundation went to citizens in twenty-two countries, while all of those of the General Education Board were held by citizens of the United States.

Of the \$110,000 set aside for the grants in aid in medical sciences in 1936, \$109,191.80 was distributed in fifty separate grants, the largest of which was \$6,000 and the smallest \$150. The grants were practically all in the field of neurology and psychiatry, or other subjects as they related to neurology or psychiatry.

During the year the foundation granted small sums from a general fund available to all divisions to the Medical College of Virginia, Tufts College Medical School and the University of Bern, Switzerland to enable each of these institutions to establish on its staff a European scholar who for political reasons, was not able to continue his research and teaching in his former post. A final contribution of \$150,000 was given to the committee on drug addiction of the National Research Council, which the foundation has been assisting since 1931. Carried on chiefly in the Universities of Virginia and Michigan, it is likely that the committee's work when completed, will represent one of the most exhaustive studies of narcotics and drug addiction as yet undertaken, the report states. The U S Public Health Service is cooperating.

Sept 11, 1937

Menopausal Arthritis

The existence of menopausal arthritis is not generally recognized. But in a presidential address to the Yorkshire Branch of the British Medical Association, Dr Geoffrey Holmes declares that through twenty years of special practice he has become familiar with it and he has been selected by the editor of the British Encyclopedia of Practical Medicine, Sir Humphry Rolleston, to write the article on this subject. Dr Collins, rheumatism research fellow of Leeds University, informed Holmes that in a four months tour of the principal rheumatism clinics in America last year he never heard menopausal arthritis mentioned. Dr Holmes limits the term 'menopausal arthritis' to arthritis beginning within the five or six years preceding or following the cessation of menstruation. The onset is insidious, at first there is little inconvenience, and medical advice is not sought until the occurrence of a sudden exacerbation of pains in the knees or hands, the joints most commonly affected. Painful swelling of the terminal joints of the fingers may cause the patient to fear the onset of rheumatoid arthritis, and the distinction is important. These patients do not look toxic or anemic or otherwise ill. The knees are almost invariably affected, causing discomfort in rising from low chairs and in standing or walking for long periods, particularly in going downhill or downstairs.

In the early stages the joint signs are exactly like those of other forms of chronic synovitis. Palpation will show that the synovial membrane on the inner side of the knee is thickened and tender. Flexion and extension of the knee give a sensation to the hand over the knee cap of soft velvety crunching. There is seldom sufficient fluid to cause riding of the patella, but the knee is enlarged. The joint is not hot. X-ray examination in the early stage does not show any bony changes or increased density of the surrounding tissues. Later bony spicules appear and still later pipping and loose bodies. The changes are then indistinguishable from those of ordinary hypertrophic arthritis and with early treatment should not be reached. The appearance of the hands also is characteristic. The wrists may be affected, but usually the joints picked out are the carpometacarpal joints of the thumbs and the terminal finger joints. The periarticular infiltration gives a somewhat elastic feeling. There may be signs of thyroid deficiency, ranging from small localized patches to well defined myxedema, brittle hair on the scalp, thinning or absence of the outer half of the eyebrows and dry harsh skin.

The most important diagnostic point is not to mistake these menopausal enlargements of the terminal finger joints for rheumatoid arthritis, in which there is usually symmetrical spindle shaped swelling of the proximal joints with muscle wasting, especially of the interossei and often trophic changes of the nails. The fingers are usually blue or very pale and cold, and the palms often wet with clammy sweat. In rheumatoid arthritis, X-ray examination shows rarefaction and narrowing of the joint slits comparatively early.

The treatment requires complete investigation of the patient. Infection, trauma and endocrine deficiency are the main causative agents of arthritis, and of these infection plays a less and trauma and endocrine deficiency a greater part in menopausal than in atrophic arthritis. Though the patient's appearance does not suggest infection, focal infection may coexist. Obvious septic foci, such as decayed teeth, should be removed. Constipation should be treated. In overweight patients, reduction of carbohydrates or of total food is usually beneficial. Vitamins B and D with, if necessary, a calcium salt may be given. As trauma plays a part, flatfoot or valgus in heavy persons

should be treated. Kneeling should be avoided. A daily hot bath, in which the patient should massage her joints, is helpful. Thyroid is indicated when signs of myxedema occur. Estrogen may be useful. Massage will aid in the removal of patches of fibrositis. Steam baths to the arms and legs, followed by massage, are particularly helpful.

The Prevention of Blindness

In a circular issued by the Ministry of Health to county councils and local health authorities, attention is drawn to the report on the prevention of blindness by the standing committee of the Union of Counties Associations for the Blind. The committee emphasized the importance of adequate antepartum supervision stressing the need for expert ophthalmoscopy in cases of failure of reading sight during pregnancy. It insisted on the proper cleansing of babies' eyes at birth and recommended a 1 per cent solution of silver nitrate as the most efficient prophylactic, though its use need not be routine. The committee held that ophthalmia neonatorum could best be treated in the hospital and that an ophthalmic surgeon should be made available at all hospitals where it was treated.

With regard to children under school age, the committee noted the success of the system of medical examination. The arrangement whereby some local authorities utilize the services of the school clinics and of the ophthalmic surgeon attending these for the examination of children under school age was thought economical and capable of expansion. The committee also recommended that the treatment of external eye conditions and the minor ailments of children of school age should be made available for children under school age and suggested that a critical survey by the health officer of the arrangements for the early diagnosis and treatment of serious eye defects in such children might be fruitful. With regard to children of and over school age, attention is drawn to the ophthalmic services provided by the local health authorities for children of school age as described in the report of the chief medical officer of the board of education on the health of the school child, in which it is recommended that school medical officers should examine children's vision as soon as possible after their entry into the school. Attention is also drawn to the possibility of serious eye trouble resulting from certain infectious diseases, especially measles.

Research on Trypanosomiasis

The problem of trypanosomiasis in Nigeria and Tanganyika is exercising the government, which has made a grant of \$95,000 a year for five years to deal with the disease in the former colony and one of \$58,000 in the latter. In Nigeria the disease is causing not only depopulation on a distressing scale but also a decline of the efficiency of the remaining population in the affected areas. A scheme has been devised to cover not only mass surveys and the treatment of nearly 100,000 people a year but also clearing and resettlement of the population in tsetse-free areas. The report pays a tribute to the research work of Dr J. F. Corson on *Trypanosoma rhodesiense* at Tinde, Tanganyika, which has been in progress for some years. It raises the immediate issue of the relation of human trypanosomiasis to the disease in domestic animals in a wild state and the part they may play as reservoirs of the infection. In the course of experiments directed toward establishing the transmission of trypanosome strains through animals to man, Dr Corson, his assistant Mr H. C. Smith of the veterinary department and an African assistant exposed themselves to inoculation from infected animals. As a result, Dr Corson and the African assistant acquired trypanosomiasis, thus showing that the trypanosome strain had not lost the power to infect man through a lengthy stay in the bodies of animals. This research is held likely to benefit not only Tanganyika, where the disease is a great obstacle to the development of large areas of the country, but also other parts of the empire.

PARIS

Sept 11, 1937

Free Hospital Service and Votes for Politicians

There is a constantly growing wave of complaint against the extension of free hospital care to those well able to pay for it. At first this abuse was chiefly confined to the larger cities of France, but there is abundant evidence to show that it is assuming huge proportions in villages. Quite often well-to-do patients are sent to the nearest public hospitals as free patients by the mayors or aldermen of smaller communities in order to obtain votes at subsequent elections. A number of examples of such abuses have recently been published in the *Concours medical*, which journal advises practitioners to file protests through their local societies. Until recently, only medical men in larger cities were affected and the country practitioner thought himself immune, but it is now his turn to feel the inroads on his income by this wave of socialization of medicine in France, which has reached alarming proportions.

Annual Meeting of International Medical Days

As in all previous sessions of this International Medical Days, the annual meeting was held June 26-30 in Paris with Professor Carnot as president. The general subject of this congress was *hormonic regulations*. The introductory paper was by Prof. G. Roussy, dean of the Paris Medical School, who said that the neuro-endocrine system exercises its action on the neurovegetative centers through four mechanisms, as follows: 1. A direct nervous mechanism, by which certain impulses are sent directly by the neurovegetative system to the organs that execute them. 2. A direct hormonal mechanism in which the hormonal principles, having entered the general circulation, act without an intermediary. 3. A central neuro-hormonal mechanism, by which the neurovegetative system acts indirectly on the organs which carry out the action by promoting the elaboration of the hormonal principles. 4. A central hormononeural mechanism in which the endocrine glands act indirectly on the organs by stimulating the function of individual neurovegetative centers.

Professor Mauriac of Bordeaux called attention to the number of unknown factors that still exist in endocrinology and how difficult it is to apply clinically the results of experimental research. Nevertheless the treatment of diabetes mellitus and diabetes insipidus, pernicious anemia and Addison's disease has made great progress. Endocrinology has furnished much valuable information on acromegaly and von Recklinghausen's disease. Perhaps psychic disturbances will be found to be due to endocrine dysfunction. In many clinical cases it is difficult to say which endocrine gland is involved and our notion of pluriglandular syndromes is evidence of our lack of knowledge from a clinical standpoint.

Edgar Allen of New Haven, Conn., showed how the estrual cycle of the lower mammalia and the menstrual cycle of primates can be reproduced in ovariectomized animals by means of pure crystallized hormones, natural or synthetic. An injection of estrogen is followed by hyperplasia of the genital epithelium. The estrual cycle in animals is a succession of growth and regression phases under the influence of estrogen and can take place even in the absence of ovulation and corpus luteum formation. Estrogen is essential to menstruation and the corpus luteum hormone, progesterone, is of secondary importance, nevertheless the development of a premenstrual state in the endometrium necessitates the action of both estrogen and progesterone.

P. E. Smith of New York pointed out the difficulty of determining the number of hypophyseal hormones. There is a striking contrast between the number, at present eight, of alleged different principles and the small number of cells, of which

only the acidophile and basophile appear to be secreting cells. All these hormones are not to be considered definite chemical entities, as they have as yet not been isolated in a pure state.

Alexis Carrel of New York described the culture method for viscera in the Lindbergh apparatus. An organ or anatomic region is transplanted in an aseptic manner and its nutrition maintained by means of a liquid injected into the main artery. The underlying principle differs from that of ordinary culture of cells, as independent units, in being a culture of constituent organ units of the body. The objective is to observe the influence of surrounding physical conditions and the composition of the circulating medium on the structural and functional activity of the organs, hence it is particularly applicable to the endocrine glands. The distinguishing feature of the Lindbergh apparatus as opposed to classic perfusion methods is the long duration of the experiment, up to a month, and the avoidance of infection. It is possible to avoid embolism and necrosis. The physical and chemical properties of the circulating medium were given. Circulation of the liquid and its chemical composition can be regulated at will. Certain glands which, like the kidney and testis, require a great deal of oxygen, degenerate rapidly.

Drs. Houssay and Biasotti of Buenos Aires stated that the hypophysis has a regulatory influence on the majority of metabolic phenomena, such as the specific dynamic action of the proteins, regulation of salt and water metabolism and the metabolism of proteins, fats and carbohydrates. They emphasized the action of the hypophysis on carbohydrate metabolism and especially of the diabetogenic hormone, which acts directly without intermediation of the pancreas.

Dr. L. Ruzicka of Zurich, Switzerland, stated that his chemical studies of various hormones, especially the androgens, had shown that they were all derived from cholesterol and that a close relation existed between so-called sex hormones and vitamins.

Ancel of Strasbourg demonstrated the action of the sex hormones in sexual development during embryonic life in the higher vertebrates. These substances may not only act on the secondary sexual characteristics but regulate the development of the genital ducts and determine the sex of the gonad. The difference in chromosomal constitution of the gonocytes in the two sexes may in a measure be overcome by excess estrogen or androgen. Intersexuality may be determined by the simultaneous secretion of both estrogen and androgen in an organism genetically male and female or possibly by the secretion of an intermediary hormone.

Von Euler of Stockholm called attention to the relations existing between hormones and vitamins. There appears to be no sharp line of demarcation between these substances. Just as vitamins can be synthesized in animals from provitamins of vegetable origin, so the hormones can be synthesized from pro-hormones of vegetable origin.

The conclusions, from a clinical standpoint, to be drawn from all the papers on hormones were the subject of discussion by Professors Loeper and Harvier of Paris. The former indicated the important interrelations of the glands of internal secretion. Instead of the terms "hypofunction" or "hyperfunction," that of "dysfunction" is to be preferred in many cases. The importance of neurohormonal relations was strongly emphasized. The prominent part played by glandular inter-reactions may make it very difficult to make a diagnosis of hormonal insufficiency. The hormonal tests themselves quite often point to an involvement of several rather than of a single gland.

Professor Harvier said that it is necessary to employ estrogens cautiously on account of their potential cancer-producing properties. Endocrine therapy is still a mysterious field and there are still many unknown elements in it.

Recent Legislation on Industrial Diseases

An outline of the work thus far accomplished by the International Bureau of Labor, with headquarters at Geneva, appears in the August 25 issue of the *Presse medicale* by Prof. L. Crozzi, head of the industrial hygiene section of the bureau. In the study of the relation between labor and the worker, the bureau has devoted attention to (a) the coordination of the tasks demanded to the aptitudes of the individual, (b) how the environment can be improved so that the maximum result is obtained without an excessive expenditure of muscular force, (c) daily and weekly duration of work, rest periods and annual vacations, (d) the investigation of how best to arrange the meals taken during a working day, and (e) adaptation of the worker to the machine and vice versa. The standards of hygiene established in 1928 have been favorably received by employers and workers in a number of countries, especially those studies which take up the question of lighting in factories, color tests and hygiene in mines. Prohibition of the use of white phosphorus in the manufacture of matches has been adopted by thirty-four countries, yet there are great risks of phosphorism and its compounds for workers in making fireworks in countries that have not adopted these precautions. Lead poisoning is another subject which has received a great deal of study by the bureau, also prevention of anthrax from wool and hides containing the spores of this type of infection, and cancer in aniline workers. The bureau issues a bibliography every three months, which contains 3000 references annually. Another problem taken up by the bureau is compensation for occupational diseases. In 1925 there were only two intoxications, lead and mercury, and one infection, anthrax, that should be compensated. Since 1934 the list has included also silicosis, intoxications by benzene and its derivatives, phosphorus, arsenic, nitro and amine derivatives, halogen derivatives of the hydrocarbons, effects of radium, radioactive substance and x-ray effects, and finally primary cancers of the skin.

Pulmonary Embolism

A report of a six year experimental study of pulmonary embolism in general and that following operations or deliveries in particular was presented by Dr. Pierre Bardin at the June 23 meeting of the Academie de chirurgie of Paris. It has been customary to say that a sudden death corresponded to a massive embolism, that subacute symptoms indicated an embolus of medium size, and that in patients presenting only hemoptyses the emboli were minute. It is evident in view of recent experimental research that such a division is inadequate. The essential in the study of pulmonary embolism is to know the mechanism of these accidents and to attack the problem in its anatomic-clinical and physiologic aspects.

Bardin distinguishes four principal clinical forms or groups, thus:

Group 1 Sudden death from syncope. This is much rarer than has been generally believed and there has been too much of a tendency to ascribe every sudden death after operative intervention to pulmonary embolism. Would it not be more correct to say that the patients succumb in reality to disturbances of the nervous system, heart, liver, kidneys or adrenals? The sudden occurrence alone does not justify making a diagnosis of embolism.

Group 2 In this group, death takes place in four or five minutes, the principal clinical symptom being anxiety. The patient complains of a severe pain in the chest but is especially overwhelmed by the impression of impending death. The face is pale but not cyanosed. The breathing is shallow but there is no asphyxia. The clinical picture is more like that of angina pectoris.

Group 3 The principal clinical feature is asphyxia. The course is much slower than in the preceding form and death takes place at the end of half an hour, one hour or longer. The patient is cyanosed and the dyspnea is marked. The exam-

ination of the lung and the evolution of the clinical picture resemble those of acute pulmonary edema. This is the variety which has been described by Trendelenburg and also by the majority of surgeons who have attempted embolectomy.

Group 4 In this group the patient dies in a few hours, the symptoms being those of cardiovascular collapse.

Even if there are cases in which a clot was found in the pulmonary artery, which could, however, not always be proved to have originated in a femoral or iliac vein, there are others in which necropsy reveals only a minute clot in a pulmonary artery of small caliber. According to Bardin it is not so much the vascular occlusion that gives rise to the serious symptoms as it is the reflex nerve disturbances due to the presence of the embolism. An experimental study of the entire question was undertaken by Bardin, by introducing minute pearl-like pieces of enamel, paraffin and pumice stone into the venous circulation of dogs. Sudden death followed only the use of minute artificial emboli, and hence it would appear that it is not massive occlusion but a reflex of pulmonary origin, caused by the action of the embolizing particles on the nerve endings in the pulmonary arteries, that gives rise to the clinical syndrome. Later an effort was made to modify the postembolic reactions in rabbits, which are the animals to be preferred for this experimental work. When the left vagus alone is sectioned, three times as many of the artificial emboli are necessary to cause sudden death. This rises to seven times the quantity when both vagi are cut. Inversely, division of the two cervical sympathetic trunks necessitates the use of only one-fourth of the quantity. In dogs and rabbits, Bardin and Delarue, by section or by chemical or mechanical irritation either of the vagus or of the trunk or ganglions of the sympathetic, have been able to reproduce pulmonary changes such as congestion, hemorrhage or edema, diffuse or localized, similar to those seen following pulmonary embolism. Bardin is of the opinion that the clinical syndromes of pulmonary embolism are not the result of a mechanical occlusion but that the embolus provokes a true reflex, beginning in the arteriole with formation of an infarct and reflex action primarily on the respiratory and then on the cardiac centers. The author was skeptical as to the results of the Trendelenburg operation of embolectomy. In the subacute and hyperacute forms, atropine sulfate and morphine hydrochloride should be given immediately. In the syncopal form with arrest of respiration, artificial respiration and, if needed, intracardiac injection of epinephrine should be associated. In the acute pulmonary edema form, ample bleeding and ouabain by the intravenous route appear logical. In the fourth, or cardiovascular collapse, type, atropine and epinephrine are indicated. His observations on dogs have shown that by giving atropine, ephedrine and sodium bicarbonate before operations, it is possible to prevent postoperative embolism. This work still requires a great deal of clinical application in order to corroborate it.

Death Following Use of Iodized Oil

At the April 29 meeting of the Societe de neurologie a case of compression of the cervical portion of the spinal cord was reported by Drs. Alajouanine and Horner in which cerebral and diffuse vasomotor dysfunction symptoms and a rise of temperature to 108.6 F and a fatal termination followed a subarachnoid injection of iodized poppy-seed oil. The neoplasm, a fibrosarcoma, seated at the level of the seventh cervical vertebra, had given rise to a transverse myelitis with marked local circulatory disturbance and a diffuse edema of the cerebral meninges, of the floor of the third ventricle, predominantly. The authors did not wish, in reporting the case, to discredit the Sicard method of diagnosing spinal cord lesions but simply to call attention to the fact that every lumbar puncture, in acute cervical medullary lesions with compression, is apt to be followed by death at some stage of the disease. They compared the vasomotor dysfunction and hyperthermia observed

in their case to the pallor-hyperthermia syndrome recently reported here as following operation in younger persons. In such cases the authors have found an edema, predominantly at the level of the floor of the third ventricle, where the vasomotor and heat regulatory centers are located. The discussion following the reading of this paper was a very active one.

Dr Baudouin was of the opinion that the use of iodized oil was without any danger in the majority of cases but that accidents are seen from time to time. Suboccipital puncture, even when iodized oil is not used, is not without its dangers, but lumbar puncture is less apt to be followed by complications. Dr Alajouanine believed that there were special reasons in his case why the injection had been followed by death. Even a simple decompression by lumbar puncture might have been fatal. Iodized oil is not very well tolerated in cases of non-tuberculous or tuberculous spinal cord compression.

Dr Mollaret asked why it would not be advisable to inject the oil at a much lower level and then place the patient in a horizontal position, so as to allow the solution to keep away from the tumor.

Dr Alajouanine replied that every procedure would be dangerous in such cases as he had reported.

Dr Chavany had observed accidents following injection of iodized oil in Dr Clovis Vincent's service. He preferred using it just before operation.

International Rheumatology Meeting

The 'International Rheumatology Day' organized by the French League Against Rheumatism will hold its meeting October 9 in Paris. The president is Professor Laignel-Levastine and the subject for general discussion is "Radioactive Preparations in Rheumatology." A clinical session at the Hôpital St Antoine will take place in the service of Professor Loeper, and in the afternoon papers will be read on Radioactive Medication by Dr Coste, on Artificial Emanotherapy by Drs Cluzet and Thiers, and on Emanotherapy in Thermal Cures by Drs Piery, Milhaud, Euziere and Castagne.

Developments in the Public Health Service

Several interesting reports were submitted to the recent national convention of the public health service physicians. The minister of the interior discussed the objectives and programs of the German public health service, as well as public health problems in general. The supreme function of public health service, he said, is the promulgation of policies consistent with the eugenic progress of the nation. The increase in the number of births from 993,126 in 1932 to around 1,290,000 in 1936 he hailed as a first victory over celibacy and the one-child system. Decisions under the sterilization law should not be made according to a narrowly medical point of view or according to whether the person in question has proved his worth in life, but rather they should be based on larger considerations of public good and on a careful appraisal of the total value of both the individual person and of his family. The marriage advisory service should be yet further expanded. Thus far there have been established within the reich 745 eugenic health centers, 655 of which are under state and ninety of which are under communal control. During the first year following the establishment of these centers 333,000 applicants for marriage subsidies and 40,000 applicants for rural homesteads were there examined. Other of the centers' activities were 150,000 advisory interviews on problems of eugenics, constant supervision of 7,500,000 school children, group examinations of 2,500,000 school children and special observations on 500,000 school children. Antituberculosis centers to the number of 1,817 cared for 1,361,000 persons, 1,068,000 x-ray examinations and 605,000

other laboratory tests were there performed. More than two thirds of all nurslings in Germany were examined by the infant welfare service. Other branches of public health activity performed services for another 1,500,000 citizens. Altogether advice was dispensed to more than 7,000,000 persons.

The speeches of other ministerial officials illustrated to what an extent the care of the pregnant woman, the mother, the nursling and the school child has come to be regarded as a public responsibility. (The German people spend annually 5 billion reichsmarks on alcohol and tobacco, this figure represents 10 per cent of the national income.) The state will also dedicate itself to other tasks, such as care of the crippled, first aid in emergencies and industrial hygiene. In protective inoculation against smallpox the incidence of more serious immunity reactions has been reduced by performance of only two vaccination incisions instead of four. The procedures of protective antituberculous inoculation are being carefully worked out, the results obtained thus far are still not thoroughly comprehensible. Among diphtheria patients the proportion of the inoculated to the uninoculated is 1:64, among the fatal cases 1:144. The program of protective inoculation already under way in some fifty municipalities may have been responsible for a decline in diphtheria mortality since December 1936. The antituberculosis campaign has become a responsibility of the public health authorities. In accordance with the four year plan, an organized campaign is being waged against deterioration and waste with respect to dwellings, clothing and food. National drainage legislation is being framed which will assure removal of sewage both liquid and solid and the maintenance of a pure water supply.

The following figures were quoted during the discussion of food supply problems. Five years ago the German farmer supplied 74 per cent of the total nutrient caloric requirement of the nation, today 83 per cent is supplied domestically. The following are some percentages of the more important domestic produce consumed in Germany: meat from 89 to 95 per cent, dairy products from 70 to 80 per cent, bacon and lard from 60 to 70 per cent and nutrient fats 55 per cent. The persistent food shortage cannot be remedied by increase in the acreage under cultivation, as there is 20 per cent too little land. An increase in the amount of produce must therefore be primarily dependent on more intensive fertilization. Besides, the nation's needs can be better met by a more strictly dietetic measure, namely, a greater attention to the vitamic content of foods. Generally speaking, the carbohydrate content of the national food supply can be increased.

Dr Conti, Berlin municipal medical counselor, contributed some interesting data on obstetrics and the present status of midwives. The number of infants born in 1936 amounted according to his reckoning, to around 1,300,000 (twins included). The confinements of 75 per cent of all the women took place at home, those of 25 per cent in hospitals, whereas during 1924 in Prussia only 9 per cent of confinements took place in hospitals. This tremendous increase in the number of hospital confinements has been even greater in particular German localities, in Berlin the rate of increase was 63 per cent and in other cities it was even so high as 90 per cent. The slightest increases were in the predominantly agricultural provinces. The causes of this increase in the number of hospital confinements are diverse: increased popular inclination to regard hospital care as superior to home care, economic advantages due to defrayal of hospital expenses by some public agency such as a sick insurance club, a greater tendency of physicians to specialize, and superannuation of midwives. According to the national health bureau the mortality of mothers was 236 per cent of those confined at home and 707 per cent of those in a hospital. Curiously enough, those regions in which only a few parturient women were hospitalized showed the lowest mortality among mothers confined at home.

Professor Kerkhous of Bonn discussed the influence of the sum of hereditary and environmental factors on the development of the bite. According to his data, 97 per cent of the German people are affected with dental caries and more than 50 per cent with anomalies of the bite. Since obviously there is no racial immunity to caries and no criteria whatever exist for a peculiarly hereditary caries, a program of general prophylaxis should be initiated, based on a dietary rich in minerals and vitamins for the periods of pregnancy and lactation. Young children should receive a similar regimen and, in their case, the food should be solid enough to provide the bite with real work.

Hospital Statistics

According to the aggregate of available statistics, the total number of independent institutions for the sick within the German reich declined to 4,864 in 1935 against 4,921 in 1934, a drop of fifty-seven. These institutions were classified as shown in the following table:

Classification of Institutions

Year	Public	Charitable	Private
1934	2 187	1 516	1 218
1935	2 132	1 562	1 170

Despite the closing of fifty-seven hospitals the number of regular beds in all the hospitals of the reich increased in 1935 by 17 per cent compared with the year 1934 (1934 604,447 beds, 1935, 614,888 beds). A not inconsiderable increase took place in the number of patients treated, from 4,628,620 in 1934 to 4,993,988 in 1935. The number of hospital days increased from 168,600,000 in 1934 to 175,600,000 in 1935, namely by 4.2 per cent. At the same time the average stay in hospital per patient receded from 46.4 days to 35.2 days. In 1932 it had amounted to 39.3 days and even in 1933 to 37.4 days. In spite of the reduction in the average stay in the hospital, a constantly growing demand for beds has developed within the past three years.

Studies of Tuberculosis of the Skin

The dermatologic clinic of Giessen University has been particularly interested in the therapy of lupus and has gradually evolved a special routine. But as Prof. Walther Schultze, ordinarius in dermatology at Giessen said in the local medical society, the older therapeutic methods that have stood the test of time are still utilized. The main objective is to attain an abbreviation of the period of treatment without impairment of favorable end results. Of the general measures that of the special dietary is consistently followed. The patients are placed on a regimen rich in vitamins but poor in common salt. The overfeeding formerly in vogue is avoided. The patients also receive air baths and sun baths. Carefully planned heliotherapy has proved itself thus far the most beneficent measure. No treatments with artificially produced light have yet shown results comparable to those obtained by exposure to sunlight. In winter and at other times when the sun's light is lacking, the patients are submitted to general light baths, quartz mercury lamps of the type devised by Jesionek, former head of the clinic, or energy carbon arc lamps are used. In addition the lupus patients are given frequent baths of other kinds and massage. They engage in sports and are kept as active as the plan of therapy permits. For local treatments the Kromayer lamp is employed. Roentgenotherapy is rejected because of its unfavorable effect in lupus cases. Conversely a combination of grenz ray irradiation and planar excision of the disease foci with the diathermic snare has proved valuable, although neither of these procedures, if administered alone, will exert a particularly favorable influence. The combined therapy leads to more speedy cure. Favorable end results are of course predicated on an extremely meticulous technique, including careful measurement of the grenz ray dosage. The freshly excised surfaces of single foci of the disease are usually irradiated with 4,000

roentgens, of intensity of either 9 or 12 kilovolts. This procedure is repeated two or three times within the course of several weeks, so that each focus receives in all no more than from 10,000 to 12,000 roentgens. This therapy is not indicated for patients who have sustained injury due to rays, especially persons who have previously been submitted to radium or roentgen irradiation. Such patients are treated with the quartz lamp or carbon arc lamp. The latter has been proved of especial cosmetic value in after-treatment, as it leaves no disfiguring scars. The most satisfactory results are obtained in patients who have not previously undergone some unsuitable treatment.

ITALY

Aug 15, 1937

The Physician and the State

Prof. Francesco Pentimalli, director of the Istituto di patologia of the University of Naples, recently spoke in parliament on the relations between physicians and the state. He said that medicine has to be organized in a corporative form so as to give medical care to all persons who need it but are not able to pay for it, the same as is given soldiers and sailors. Farm hands receive medical care and hospitalization during the time they are giving services, whereas, when they are not, they have to resort to municipal or charitable hospitals. The speaker advised changing the laws by creating a ministry of sanitation for concentration of the various health departments that now form part of different ministries. He reviewed the organization of the antituberculosis departments. He advised carrying on systematic Pirquet cutaneous reactions in school children in order to be able to detect tuberculosis early and separate the affected from the healthy children. The Opera Nazionale per la Maternita e Infanzia carries on a praiseworthy work. However, it could be increased in the country in order to provide for the needs of mothers and children of the rural districts. The infant mortality from nutritional diseases is still high in rural areas because of the fact that mothers are not informed concerning the care and feeding of infants. Municipal physicians are prepared to meet the problem by courses of infantile pathology which was required during their university studies but feeding, education and social care of infants were not given the proper importance. The speaker pointed out the importance of establishing special courses of puericulture in all universities, the passing of which will be an obligation for those who apply for positions as municipal physicians.

Laws on Industrial Accidents

The laws on accidents resulting from work were recently reformed. Formerly the indemnity was restricted to the accident itself and was proportional to the injury. The benefit of the insurance was allowed only to those working in dangerous industries. By the new laws attention is given less to paying indemnities than to preventing accidents and industrial diseases and, in case they happen, to the administration of medical care and industrial reeducation for restoration of the working capacity of those either injured or ill. The benefit of insurance is given to those employed in any industrial, commercial or agricultural work which is lawful and of which there are about twenty types. Provisions are made for treatment and compensation of workers suffering from diseases contracted in the course of work. The definition of the words 'industrial accident' from a medicolegal point of view, is unchanged. It includes two causal factors "violence" during "work." The system of paying indemnities is also changed. Those insured will be given an annual allowance instead of the total amount of money that was previously paid. In cases of total permanent invalidity the annual allowance will be half the annual salary of the worker. The amount to be paid for temporary invalidity is two thirds the monthly salary. It was half the salary, according to the old law. Slight lesions with a short period of work-

ing incapacity are given little economic aid if any. The new laws sanction the view that those insured and suffering from industrial accidents cannot refuse medical treatment or operations which are deemed necessary by the insurance physician unless they give justifiable reasons in refusing the treatment. The insurance centers are responsible, by the new laws, for the expenses involved in hospitalization, medical treatment and industrial reeducation of those incapacitated from work. In this category men with working capacity reduced at least to 80 per cent from industrial accidents are included.

Bronchoscopy

Professor Malan, director of the Clinica otorinolaringoiatrica of Turin, recently gave a lecture to the military physicians in the city on the diagnostic and therapeutic value of bronchoscopy. Malgaigne, Trousseau and other physicians of the fourteenth century were the first ones to think of the possibilities of introducing certain instruments and liquids into the bronchi. The first bronchoscopy was made by Killian in 1895. The technic has been improved and the knowledge on the subject intensified. The operation was at first restricted to the removal of foreign bodies. Now it is indicated for the diagnosis and treatment of several diseases of the respiratory tract. In Chevalier Jackson's clinic at Philadelphia, 80 per cent of the bronchoscopies done are performed according to medical indications. The presence of cachexia, advanced tuberculosis, acute pneumonia, recent hemoptysis and grave pleuritis are, as a rule, the only contraindications. Jackson's bronchoscope carries a small lamp at its distal flute-mouthlike end which gives distal illumination to the bronchoscopic field with consequent visual control of the field and facility for work. The patient is placed in the dorsal position with the head out of bed and maintained by a special support at an inclination which can be regulated by the assistant. The operation is done with local procaine hydrochloride anesthesia of the larynx and bronchi. Bronchoscopy is indicated in spasms, hemorrhage and obstruction of the bronchi. The operation is indicated for the diagnosis and treatment of certain types of pulmonary suppurations, without proscribing medical treatment or other operations if they are indicated. It does not give satisfactory results in gangrene of the lung. Bronchoscopy induces complete recovery of patients suffering from acute abscess of the lung in 70 per cent of the cases, especially if the abscess is located at the parahilar region. Complete recovery from the operation is attained by only 50 per cent of patients who are suffering from subacute infection of the lung and in 20 per cent of the patients suffering from chronic suppuration of the lung. In cases of advanced bronchiectasis with auto-intoxication and cardiac insufficiency, bronchoscopy induces the so-called social recovery of the patients, by which the latter can work and be in society, in 50 per cent of the cases. Bronchoscopy gives also satisfactory results in the so-called postoperative atelectasis.

Marriages

ALEXANDER WILLIAM ADAMSKI, South Milwaukee, Wis., to Miss Katherine Margaret Poborsky of Milwaukee, June 26.

HENRY G. REYNOLDS, Paducah, Ky., to Mrs. Grace Morrison Poole of Ossining, N. Y., September 29.

CRAIG WRIGHT MUCKLE, Haverford, Pa., to Miss Christine Murdoch Kendrick of Philadelphia, June 3.

WILLIAM H. FICKEL, Las Animas, Colo., to Miss Helen Elizabeth Carlson of Denver, August 25.

GEORGE WILLIAM HEINTZELMAN to Miss Eva Louise Kuhns, both of Schnecksville, Pa., June 11.

EMANUEL M. ARNOVITZ to Miss Margaret F. Beck, both of Granite City, Ill., August 11.

MARVIN E. ARRINGTON, Vaiden, Miss., to Miss Edythe Dec of Gulfport in Jackson in July.

Deaths

Charles Ludvey Davis, Pasadena, Calif., St. Louis University School of Medicine, 1908, member of the American Academy of Ophthalmology and Oto-Laryngology and the Pacific Coast Oto-Ophthalmological Society, served during the World War, formerly instructor in clinical otology, Washington University School of Medicine, St. Louis, at one time assistant otolaryngologist to the Barnes Hospital and St. Louis Children's Hospital, St. Louis, surgeon to outpatients Washington University Dispensary, St. Louis, surgeon to St. Louis City Hospital and consultant to Barnard Skin and Cancer Hospital, St. Louis, aged 53, died, July 25, of cerebral embolism.

Charles August Bentz of Buffalo, University of Buffalo School of Medicine, 1902, assistant professor of medicine at his alma mater, member of the American Association of Pathologists and Bacteriologists, Society of American Bacteriologists and the American Society of Clinical Pathologists, director of the division of communicable diseases of the city department of health and superintendent of laboratories, at various times on the staffs of the J. N. Adam Memorial Hospital, Perryburg, Buffalo Eye and Ear Infirmary, Buffalo Hospital of the Sisters of Charity, Memorial Hospital and St. Mary's Maternity Hospital, aged 58, died, July 25, of endocarditis.

Samuel Dana Hubbard, Freeport, N. Y., Bellevue Hospital Medical College, New York, 1891, for many years director of public health education, city board of health of New York, formerly professor of hygiene and sanitation, New York Medical College for Women, veteran of the Spanish American War, at various times on the staffs of the New York City Children's Hospital, New York, the Letchworth Village, Thells, and the Vanderbilt Clinic, New York, author of a treatise on diseases of the hair and scalp, aged 68, died July 12, in the New York Hospital, of carcinoma of the stomach.

Frederic Bierhoff of New York, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1889, member of the American Urological Association, fellow of the American College of Surgeons, consulting cystoscopist, Gouverneur Hospital, genito-urinary surgeon to the Home for Aged and Infirm Hebrews, aged 69, died, July 31, in Blue Hill, Maine.

Charles Milton Clark, Akron, Ohio, Medical College of Virginia, Richmond, 1913, member of the Ohio State Medical Association, served during the World War, formerly in charge of the department of biology, and college physician at the Hampden Sidney (Va.) College, on the staff of the Akron City Hospital, aged 47, died, July 22, of carbuncle and septicemia.

Charles Hunter Cunningham, Auburn, Maine, Medical School of Maine, Portland, 1909, member of the Maine Medical Association and the Radiological Society of North America, fellow of the American College of Surgeons, consulting surgeon to the Central Maine General Hospital, aged 54, died, July 14, of cerebral hemorrhage.

Charles William Bray of Biwabik, Minn., University of Minnesota College of Medicine and Surgery, Minneapolis, 1895, formerly vice president of the Minnesota State Medical Association, for many years president of the school board, medical superintendent and owner of the Biwabik Hospital, aged 68, died, July 7, of coronary disease.

Bernhard Gustav Harff, Cincinnati, Rheinische Friedrich-Wilhelms-Universität Medizinische Fakultät, Bonn, Prussia, Germany, 1875, formerly a member of the board of trustees of the University of Cincinnati, aged 89, died, July 14, in St. Francis Hospital, of compound fracture of the ribs and puncture of the lung.

Alonzo Clark Hunt, Metuchen, N. J., College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1881, member of the Medical Society of New Jersey, for many years a member of the state board of health, aged 78, died, July 13, in Mantoloking of an accidental gunshot wound.

Thomas Joseph Flynn of Colonel, M. C., U. S. Army, St. Louis, Albany (N. Y.) Medical College, 1905, entered the Medical Corps of the U. S. Army as a first lieutenant in 1911, was promoted through the various grades to that of lieutenant colonel in 1931 and in 1937 a colonel, aged 56, died, July 4.

Harriet Elizabeth Balch-Holmes, Pequanock, N. J., Woman's Medical College of the New York Infirmary for Women and Children, 1897, for many years on the staff of the Craig Colony, Sonyea, aged 67, died, July 25, in Oakland of paralysis agitans, nephritis and arteriosclerosis.

Charles Sawyer Bryant, Millinocket, Maine, Harvard University Medical School Boston 1900, member of the Maine Medical Association, served during the World War, owner of a hospital bearing his name, aged 63, died, July 17, in the Eastern Maine General Hospital, Bangor

James Vickers Anglin, St John, N B Canada, Queen's University Faculty of Medicine, Kingston, Ont, 1887, member and past president of the American Psychiatric Association, for many years superintendent of the Provincial Hospital at Fairville, aged 77, died, July 8

George Whitefield Overholser ♂ Reading, Pa, University of Pennsylvania Department of Medicine, Philadelphia, 1902, past president of the Berks County Medical Society, on the staff of the Reading Hospital, aged 63, died, July 10, of carcinoma of the pancreas

Fred Walter Comstock, New Haven, Conn, Tufts College Medical School, Boston, 1913, member of the Connecticut State Medical Society, served during the World War, on the staff of the Grace Hospital, aged 48, died suddenly, July 17, of cerebral hemorrhage

Martin John Cromwell, Ruston, Md, University of Maryland School of Medicine, Baltimore 1894, member of the Medical and Surgical Faculty of Maryland, aged 65, died, July 14, in the Johns Hopkins Hospital, Baltimore of acute pyelonephritis

Roy M Buchanan, Decatur, Ala, University of Tennessee Medical Department, Nashville, 1900, member of the Medical Association of the State of Alabama, aged 58, died, July 1, in the Benevolent Society Hospital, of duodenal ulcer and pyloric obstruction

Harry Joseph Handelman ♂ New York, Fordham University School of Medicine, New York, 1917, fellow of the American College of Surgeons, on the staff of the Fordham Hospital, served during the World War, aged 46, died, July 11

William Penn Coyle ♂ Orange, Texas, Southwestern University Medical College, Dallas, 1906, formerly a dentist, city health officer, served during the World War, on the staff of the Frances Ann Luther Hospital, aged 58, died, July 31

William Brown Doherty, Louisville, Ky, University of Louisville Medical Department, 1872, emeritus professor of obstetrics in his alma mater, aged 90, died July 25 in St Joseph Infirmary, of acute appendicitis and bronchopneumonia

Merlyn Bush Call ♂ Greene, Iowa, State University of Iowa College of Medicine, Iowa City, 1911, formerly secretary of the Butler County Medical Society, aged 54, died, July 14, in St Joseph Mercy Hospital, Waverly, of uremia

Thomas Gordon Dickson, Troy, N Y, University of Pennsylvania Department of Medicine, Philadelphia, 1891, veteran of the Spanish-American War, formerly on the staff of the Troy Hospital, died, July 8, in the Samaritan Hospital

Frederick John Bowen, Mount Morris, N Y, College of Physicians and Surgeons of Chicago, 1890, member of the Medical Society of the State of New York, for many years county coroner, aged 71, died, July 28, of lymphosarcoma

Claude Jacob Bradshaw, Carrsville, Va, Medical College of Virginia, Richmond, 1892, member of the Medical Society of Virginia, aged 68, died, July 27, in the Lakeview Hospital, Suffolk, of coronary occlusion and hypostatic pneumonia

Franklin Austin Knope ♂ Rochester, N Y, University of Buffalo School of Medicine, 1917, fellow of the American College of Surgeons, served during the World War, attending surgeon to the Highland Hospital, aged 42, died, July 3

William A Clark, Bald Knob, Ark, St Louis College of Physicians and Surgeons, 1892, member of the Arkansas Medical Society, past president of the White County Medical Society, aged 69, died, July 8, of cerebral thrombus

Eva St Clair Osburn Barber, Los Angeles, College of Physicians and Surgeons, Keokuk, Iowa, 1886, at one time on the staffs of St Joseph's and Tacoma General hospitals, Tacoma, Wash, aged 80, died, July 5, of bronchopneumonia

Henry Nehemiah Dodge, Morristown, N J, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1868, also a dentist, aged 94, died, July 24, of cerebral hemorrhage and arteriosclerosis

William Clayton Whittenberg, Stillwater, Okla, St Louis College of Physicians and Surgeons, 1900, veteran of the Spanish-American War, owner of the Stillwater Hospital, aged 66, died, July 1, of mesenteric thrombosis

Benjamin Harvey Carlton, Donalds, S C, University of Georgia Medical Department, 1894, member of the South Carolina Medical Association, for many years bank president, aged 66, died, July 22, of coronary occlusion

William Wilder Hopkins ♂ Geneva, N Y, New York Homeopathic Medical College and Hospital, New York, 1893, formerly on the Geneva General Hospital, aged 67, died, July 5, of coronary occlusion

James Kester Biddle, Bend, Ore, College of Physicians and Surgeons, Baltimore, 1909, served during the World War, formerly coroner of Richland County, Ohio, aged 53, died, July 25, in a local hospital

Robert C Ellis, Shelby, N C, Baltimore University School of Medicine, 1886, member of the Medical Society of the State of North Carolina, aged 80, died, July 25, of carcinoma of the stomach

Herman Shube ♂ Cleveland, Cleveland College of Physicians and Surgeons, Medical Department Ohio Wesleyan University, 1910, formerly on the staff of St Luke's Hospital, aged 51, died, July 5

Charles Alexander Campbell, Jamaica, N Y, Bellevue Hospital Medical College, New York, 1897, member of the Medical Society of the State of New York, aged 62, died, July 7, in New York

Robert Crawford Irwin, Hollidaysburg, Pa, University of Pennsylvania Department of Medicine, Philadelphia, 1879, aged 82, died, July 7, in the Mercy Hospital, Altoona, of carcinoma of the colon

Edgar William Alexander ♂ San Francisco, University of California Medical Department, San Francisco, 1905, member of the Pacific Coast Oto-Ophthalmological Society, aged 59, died, July 21

Marie Antoinette Bennette, San Bernardino, Calif, Cooper Medical College, San Francisco, 1885, member of the California Medical Association, aged 78, died, July 27, in a local hospital

Henry Mosley Dismukes, Minter, Ala, University of Tennessee Medical Department, Nashville, 1907, member of the Medical Association of the State of Alabama, aged 56, died, July 22

Henry Redmond, Corpus Christi, Texas, University of Pennsylvania Department of Medicine, Philadelphia, 1886, aged 77, died, July 1, of chronic myocarditis and hypostatic pneumonia

Albert Edward Campbell, Agoura, Calif, University of Buffalo School of Medicine, 1886, at one time city health officer of Springfield, Ill, and Sioux Falls, S D, aged 77, died, July 15

Earl Bell ♂ Wilmington, Del, Medico-Chirurgical College of Philadelphia, 1909, aged 56, died, July 8, in the Delaware Hospital, of pulmonary infarct and acute gangrenous appendicitis

George Randall Anderson ♂ Easton, Pa, Jefferson Medical College of Philadelphia, 1882, aged 80, died, July 23, in the Lankenau Hospital, Philadelphia, of sarcoma of the colon

David Simeon Belanger, New Bedford, Mass, School of Medicine and Surgery of Montreal, Que, Canada, 1892, aged 78, died, July 18, of diabetes mellitus and gangrene of the right foot

James R Barnett Jr, Neenah, Wis, Rush Medical College, Chicago, 1897, for many years city physician, aged 62, died, July 11, of coronary thrombosis and arteriosclerosis

George G Irwin ♂ Mount Holly Springs, Pa, College of Physicians and Surgeons, Baltimore, 1892, aged 76, died, July 10, of coronary thrombosis and chronic myocarditis

Adelbert Stephen Dederick ♂ Woodhaven, N Y Albany Medical College, 1906, on the staff of the Lutheran Hospital, Brooklyn, aged 55, died, July 17, of angina pectoris

Frederick Charles Anthes, Watertown, Mass, University of the City of New York Medical Department, 1884, aged 77, died, July 20, of carcinoma of the prostate

Calvin Norwood Wherry ♂ Upper Darby, Pa, Jefferson Medical College of Philadelphia, 1902, aged 57, died suddenly, July 7, in Doylestown, of cerebral hemorrhage

Elisha H F Farlow, Laurel, Del, Baltimore University School of Medicine, 1891, for many years mayor, aged 78, died, July 6, of myocarditis and chronic nephritis

Frederick F Davis, Sassafras, Va, Medical College of Virginia, Richmond, 1894, aged 66, died, July 18, in St Elizabeth's Hospital, Richmond, of leukemia

George Washington Bader, St Louis, Washington University School of Medicine, St Louis, 1904, aged 59, died, July 16, of coronary thrombosis

Ernst Custeen Brasington, Kershaw, S C, Rush Medical College, Chicago, 1888, aged 77, died July 29

USE OF METHYLENE BLUE IN METHEMOGLOBINEMIA FROM SULFANILAMIDE POISONING

To the Editor—In 1933 Williams and Challis (*J Lab & Clin Med* 19 166 [Nov] 1933) reported that methylene blue was effective as an antidote for parabromaniline poisoning. Shortly afterward Steele and Spink (*New England J Med* 208 1152 [June] 1933) used methylene blue in a case of aniline poisoning and also in one of acetanilid poisoning, with what they considered dramatic recoveries. Both groups of workers stated that the methemoglobinemia shown by their patients before administration of methylene blue rapidly disappeared following intravenous injection of the dye. Williams and Challis, subsequent to treatment of their patient, carried out experiments on rabbits, the results of which they considered as justification for their claim that methylene blue had been responsible for the rapid improvement of their patient. Little attention appears to have been paid these observations and the writers themselves have not commented further in the literature on what, if substantiated, would appear to be a discovery of major therapeutic importance. This is especially true now that effective therapy with sulfanilamide is, at least in some individuals, limited by methemoglobin formation.

Prior to the appearance of these papers, I had proved to my own satisfaction that methylene blue acts as an antidote for cyanide poisoning because it forms methemoglobin (*THE JOURNAL*, April 1, 1933, p 1054, *J Pharmacol & Exper Therap* 54 283 [July] 1935). It therefore seemed unlikely that methylene blue could accomplish the reverse effect. Furthermore, I was not convinced that the spectrograms published by Williams and Challis supported their claims. I find now, however, that these workers were correct in their belief that methylene blue hastens conversions of methemoglobin to hemoglobin in the circulating erythrocytes. With the assistance of Mr Charles Anderson and Miss Jane Erganian, extensive experiments have been carried out on dogs and rabbits to determine the effect of various amounts of methylene blue on methemoglobinemia produced by sodium nitrite. Briefly, we have found that intravenous injection into dogs of 5 mg of methylene blue per kilogram of body weight increases the rate of methemoglobin conversion to hemoglobin about eight or ten fold, i e., the rate is eight or ten times as fast as the physiologic rate. The physiologic rate in dogs, as determined by a series of normal controls, is about 18 volumes per cent (135 Gm per hundred cubic centimeters of blood) per hour. Larger amounts of methylene blue are more effective and smaller amounts less effective. However, 1 mg of methylene blue per kilogram of body weight increases the rate in dogs three or four fold and even 0.1 mg per kilogram has a detectable effect.

The object of our first experiments was to produce methemoglobin in animals by administration of sulfanilamide and then to investigate the possibility of controlling the methemoglobinemia by another substance. We were not successful, however, in producing methemoglobinemia with sulfanilamide in dogs and rabbits even though large doses were given and the blood sulfanilamide concentration rose in some animals to 75 mg per hundred cubic centimeters. Indeed, most of the animals showed no signs of toxicity until the blood sulfanilamide concentration reached 50 mg per hundred cubic centimeters or higher. At about this concentration dizziness appeared and increased in intensity as the blood sulfanilamide concentration rose. Methylene blue (10 mg per kilogram) injected at a time when the animals were extremely toxic did not increase the severity of the symptoms.

In the light of these observations and at my suggestion, Dr Alexis F Hartmann, professor of pediatrics at Washington

University School of Medicine, injected methylene blue into two children showing moderate degrees of cyanosis and methemoglobinemia from sulfanilamide with results comparable to those obtained in experimental animals. A single injection of 1 mg of methylene blue per kilogram of body weight reduced the methemoglobin from 20 per cent of the total pigment to less than 3 per cent of the total in forty-five minutes in one patient, and from 18 per cent to less than 3 per cent in the other in a similar period. It appears that methylene blue may be of great value in decreasing the severity of the methemoglobinemia in patients who show unusual sensitiveness to sulfanilamide. Furthermore, it seems possible that the effectiveness of sulfanilamide therapy might be greatly increased if a higher blood concentration of the drug could be maintained by means of simultaneous administration of methylene blue. Before this is attempted, however, the effect of methylene blue on the therapeutic activity of sulfanilamide and the effect of repeated administration of methylene blue on the normal animal must be determined. These questions are being investigated. Also the possibility that the methylene blue might be effective orally is being considered.

The accelerating action of methylene blue on conversion of methemoglobin to hemoglobin is catalytic. Indeed, in this reaction the catalysis is one of reduction. The possibility of using foreign oxidation-reduction systems like methylene blue to catalyze reduction processes in the body has not been considered heretofore. Methylene blue and similar oxidation-reduction systems have been added to isolated tissues or administered to animals by students of biologic oxidation processes, usually with the intent of catalytically increasing oxidation processes. It has been expected, or at least hoped, that the reduced form of the system would react with molecular oxygen regenerate the oxidized form, and thus complete the oxidation cycle. The possibility that the reduced form of the system might escape autooxidation and accomplish reduction of some cellular constituent appears to have been overlooked.

The reported results are not at variance with the evidence that methylene blue converts hemoglobin to methemoglobin and with my explanation of the antagonism of methylene blue for cyanide in the living animal based on this evidence. A supplementary and, to me, unexpected aspect of the question has been revealed.

Details of the experiments are being prepared for publication.

BETWEEN RESPIRATORY PARALYSIS AND THE RESPIRATOR

To the Editor—The present epidemic of poliomyelitis appears to present a medical emergency from the point of view of the treatment of acute asphyxia. It is well recognized that the most satisfactory form of routine artificial respiration for this type of case is by the negative pressure cabinet. There is, however, a sharp break in the link of treatment which occurs not infrequently between the period when asphyxia has developed as a result of ascending muscular paralysis and that time when negative pressure cabinet facilities become available.

Press reports would suggest that patients who are out of touch with such treatment in such an emergency perish.

My experience with resuscitation suggests the use of laryngoscopy, intubation and insufflation of oxygen under pressure as a practical means of tiding over this fatal period.

To my great astonishment inquiries directed to personnel interested in the care of such cases reveals that this technique has not been used and is not being used and that its value is not generally understood.

From repeated experience in the support of the asphyxiated patients, over hours whose respirations have completely disappeared and remain in abeyance I know that given a functioning circulation, such a patient can be cured for a period sufficient to reach a negative pressure cabinet even though it may be removed a distance of several hundred miles

PAUL H. J. FLACC, M.D., New York

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS BUT THESE WILL BE OMITTED ON REQUEST.

VACCINES IN COLDS

To the Editor—What is the present status of vaccines for colds? If they are valuable, what organisms should be used in the vaccines?

M.D. New Jersey

ANSWER—The term "colds" is a useful waste basket for those symptoms to which a specific name cannot be attached. Recent evidence indicates that true influenza can and should be sharply differentiated, and there may be other specific bacterial or virus diseases which should and eventually will be removed from this scrap heap.

All investigations to date have consistently shown a wide variety of bacteria present in colds. This fact necessitates the assumption either that colds are not due to any specific organism but that symptoms which we recognize by that term can be produced by a large number of different bacteria or that the specific cause has not yet been identified. Some colds are probably due to a specific virus. It is evident therefore that any attempt made now to produce immunity by vaccines must be aimed at a combination of organisms with the hope of chance inclusion of the right one, or that the combination also by accident contains the as yet unidentified principle which causes all colds. Neither of these possibilities seems to offer a scientifically rational approach to prophylaxis.

The duration of acquired immunity is another important question. Since the actual having of a cold seems to produce in most people at least, little if any lasting immunity to subsequent colds it would seem doubtful that vaccines could produce any more successful immunity. Even if vaccines do produce a greater immunity it would probably be necessary to administer them continuously in order to avoid rapid increase in susceptibility. All these facts apply to any of the vaccines available today either for parenteral or for oral administration.

In conclusion therefore, there is no real scientific evidence supporting the use of vaccines for the common cold. In those individual instances in which benefit seems to result this apparent effect may be due either to the individual fluctuation in frequency which is generally observed or to some nonspecific stimulation of immunity created by the administered proteins.

TREATMENT OF LYMPHATIC LEUKEMIA

To the Editor—Please send me the information you can on the treatment of lymphatic leukemia.

J. W. STECKHAUER, M.D., Manitowish

ANSWER—The treatment of lymphatic leukemia depends first on whether the case is acute or chronic. In the acute type with rapid onset, relatively low white count, young leukocytes, marked anemia and often septic temperature no treatment is known to exert any benefit. Blood transfusions can be tried. In the chronic type, with large number of relatively mature lymphocytes, treatment is similar to that of chronic myelogenous leukemia. X-rays and solution of potassium arsenite are the most effective forms of therapy. X-rays can be given over the bones or spleen until the white count is reduced nearly to normal. Treatment is again instituted on recurrence of symptoms. Solution of potassium arsenite although not so effective as the X-rays, is frequently beneficial. Doses must be increased to the point of tolerance and can be continued for from four to five weeks. Alternate use of these two remedies often proves satisfactory.

TOXIC GASES FROM DYNAMITE AND TNT EXPLOSIONS

To the Editor—A patient claims he is suffering from the inhalation of gases following the explosion of dynamite in an underground shaft. One man of a group who inhaled the gas died and now my patient seven weeks following the accident still complains of vague chest pains and shortness of breath. What gases are formed from TNT explosion and what effect would they have on the bronchial mucosa?

H. W. NOTTLEY, M.D., White Plains, N.Y.

ANSWER—This query implies that dynamite and TNT are the same sort of blasting explosive. More properly speaking, dynamite represents various grades of nitroglycerin or nitrostarch while TNT is trinitrotoluene. However, TNT is used as a blasting explosive as described in a publication by Monroe and Spencer in circular 94, U.S. Department of Agriculture, May 1920. Nitroglycerin is much more widely used as an explosive in mining operations.

The gases produced from the burning of dynamite are more injurious than those from the explosion of the same substance. In either case the chief gases produced are carbon dioxide, carbon monoxide, nitrogen oxides and rarely hydrogen sulfide or other sulfur compounds. From the explosion of trinitrotoluene large quantities of carbon monoxide may be produced, which usually renders this explosive unsuited for underground purposes.

In the accident mentioned in the query, the responsible agent is likely to be carbon monoxide, oxides of nitrogen or a mixture of the two. The condition of the miner who died should furnish clues as to the responsible gas. If marked pulmonary edema or other evidence of inflammation of the respiratory tract dominated the picture, it is likely that oxides of nitrogen were the chief offenders. Contrariwise, if the usual results of the formation of carboxyhemoglobin were presented, carbon monoxide may be regarded as the probable cause.

With regard to the workman who alleges that he is sick seven weeks after the accident, it is to be remembered that neuroses without organic involvement may arise. It is unlikely that residual manifestations are on an organic basis at this late time, unless shortly after the accident this miner was unconscious from carbon monoxide poisoning or had pulmonary edema, pneumonia or severe bronchitis as a result of the action of oxides of nitrogen. If such was the case, residual manifestations on an organic basis are possible, particularly if nitrogen oxides were present and contributed to the initial injury.

CARBON ARC LAMPS

To the Editor—1. What is the therapeutic value of the carbon arc? 2. Does it destroy bacteria? 3. Is the light made by the Landun Corporation of Terre Haute Ind. satisfactory?

DDS, Indiana

ANSWER—1. The carbon arc is one of several types of generators of ultraviolet radiation. So far as it is known the therapeutic value of all sources of ultraviolet radiation are much alike. The carbon arc is the hottest radiation readily obtainable and in this respect it is the closest approach to the sun. However the radiation from the carbon arc is far from being like sunlight. There are three important factors to be considered when using a carbon arc for therapeutic purposes: (a) the kind (impregnated material) and size of the carbons; (b) the distance between the recipient and the arc; and (c) the quantity of current. The size of the carbon and the kind of material used in the core of the carbon are important factors. The 30 ampere arc with 13 mm carbons (therapeutic C) give a quantity and quality of energy useful for therapeutic purposes. Assuming that the distance between the arc and the patient remains the same the 15 ampere arc with 10 mm carbons is only about one fifth of this quantity while the 10 ampere arc with the 6 mm carbons supplies only about one twenty fifth of the energy. This means that the radiation from the smaller carbons would take a much longer time to produce a therapeutic effect than the larger one.

2. The carbon arc has a bactericidal effect just as ultraviolet radiation from any other source. A further interpretation of this action, however, should be considered since the proof of it is established only with bacteria in petri dishes whereas its efficacy in the open wound remains to be proved. Ultraviolet radiation has been used for example in the sterilization of water in swimming pools. The diseases benefited by ultraviolet radiation are summarized in the short article issued by the Council on Physical Therapy, 'Regulations to Govern Advertising of Ultraviolet Generators to the Public.' Reprints may be obtained from the Council.

3. The lights made by the Landun Corporation of Terre Haute Ind. have not been submitted to or investigated by the Council on Physical Therapy. The Council's specifications

of minimum intensity are based on a comfortable and convenient operating distance (24 inches from the front edge of the reflector), at which distance the exposure can be made without burning the skin by coming in contact with the burner or by the infra-red rays. The ultraviolet intensity of the lamp shall be such that the time of exposure to produce a minimum perceptible erythema (one that disappears in less than twenty-four hours) will not be longer than fifteen minutes for a therapeutic lamp and sixty minutes for so called sunlamps.

POSSIBLE DIAGNOSIS OF ADDISON'S DISEASE

To the Editor—A banker aged 48, weighing 240 pounds (119 kg) and 5 feet 11 inches (180 cm) in height, with past history negative except for appendectomy about ten years ago has nervousness, irritability, marked fatigue, gas distention and fullness after eating, loss of libido and sexual power and a feeling of internal chilliness even when sufficiently covered. He is a rather obese individual with a large amount of abdominal and girdle fat. The eyes, ears, nose and throat are normal. The chest except for a fatty deposit about the breast is normal. The heart is normal with tones rather weak. The pulse is soft and weak. The blood pressure is 80 systolic, 60 diastolic. The hemoglobin was 85 per cent. The blood count was otherwise normal. Urinalysis was negative. The tuberculin skin test was positive. The skin was clear and somewhat clammy. The muscles were soft and flabby. I made a diagnosis of probable adrenal gland deficiency. During the summer I gave arsenic and strychnine hypodermically with some gland extract by mouth and the patient reacted favorably with blood pressure elevating to a systolic of 110. He came to see me about a month ago and the blood pressure was 100/68. He did not react to the arsenicals intravenously and about one week ago I began using a commercial adrenal extract. The patient was seen today after two injections with a blood pressure of 114/76. He is still nervous and irritable. The question in his mind is how do I know the diagnosis to be correct and how long will he have to be under treatment? I told him quite clearly that at autopsy I could remove the adrenal gland and see whether or not there is a simple atrophy or tuberculosis of the gland and as for the treatment he would have to be under it indefinitely. Naturally I have in mind that he has Addison's disease to a minor degree and I want to know whether there is any way to prove my diagnosis other than by his feelings after the administration of cortical extracts. M D South Carolina

ANSWER—There seems to be no evidence in this clinical record of Addison's disease. Further evidence of value might be obtained by taking an x-ray film of the adrenal glands to determine whether or not extensive calcification exists in them (areas of calcification, however, may occur in normally functioning adrenals). The level of the blood sodium and of the blood urea might likewise prove enlightening. If the evidence from these three laboratory determinations proves negative, the possibility of Addison's disease is negligible.

In view of the sensation of chilliness, the overweight and the irritability, a basal metabolism test seems desirable. If low, thyroid medication might prove helpful. It would seem desirable also to investigate the loss of libido and potentia in order to determine its cause.

SHORT WAVE DIATHERMY

To the Editor—I have followed diathermy through all the various stages and have purchased each new development mainly to get away from one thing—aching of the part during and after treatment. It is not possible to treat a joint (with no adequate heat input) without this aching. I know it is usually ascribed to excessive heating or the faradic sensation I am using a 17 meter short wave machine. Can you give me an authoritative opinion? M D California

ANSWER—The degree of heat brought about by conventional diathermy or any of the short wave machines takes place in accordance with Joule's laws. The whole technique of diathermy is based on these primary physical laws.

The aching of the part following a local treatment with diathermy or short wave machines is due to the fact that the current flow is either too strong over a short period or the treatment is given over too long a time. The pain thus produced is due to a vascular and lymphatic congestion causing pressure on the nerve endings.

From the standpoint of technique let it be assumed that the electrodes of conventional diathermy have been applied properly, are not too small or too long and are of equal size and equidistant at all points of the electrode. In other words the two planes of the electrodes should be parallel. The current flow should be turned on slowly and increased at an even rate for the first five minutes until the patient states that he is receiving a comfortable warmth. When this point is exceeded or the rise is too rapid there is too intense vasodilatation and pain naturally results. The rule which should be constantly kept in mind is that the technician should at no time exceed the patient's tolerance and should at no time permit a too rapid

rise of current flow or give a treatment over too long a period. The average time for such a treatment is one half hour.

If, during the treatment, aching or pain occurs, the current should be decreased or the time interval cut down until the patient is again comfortable.

If the aching sensation persists after the current has been turned down, the electrode should be removed and the part placed in the whirlpool or warm moist dressings applied. This will give instant relief.

The short wave medical diathermy machines that have been accepted by the Council on Physical Therapy use the cable electrode for the electromagnetic induction and the double cuff electrodes, or air-spaced electrodes placed on the same side as the part to be treated, for the electric field.

Machines that have been accepted by the Council on Physical Therapy of the American Medical Association have been checked carefully to make sure that there is no faradic sensation or neuromuscular response.

INFECTION WITH INFLUENZA FROM ANESTHESIA MACHINE

To the Editor—I should like to have some information concerning the possibility of a patient contracting influenza by being given an anesthetic with a machine which had been used on a patient in an emergency who had a mild influenza at the time. I am using a McHesson machine and am giving a nitrous oxide oxygen ether combination for general surgical operations. The machine is of the closed type. About six weeks ago it was necessary to give the influenza patient an anesthetic and since that time I have had three patients develop what was apparently a mild influenza on the second day after operation. However not all the patients given an anesthetic since that time have developed the condition.

M D Tennessee

ANSWER—The manufacturers of present day gas machines have had little help in the construction of equipment so that it will not be easily contaminated. At present the experience cited is readily possible and might easily be due to an infected gas machine. T. B. Magath has suggested the inclusion of a water trap between the patient and the gas machine, thereby saving the gas machine from contamination. The sterilization of the mask and the inhaler tubings can then be carried out and the possibility of having one patient become infected from another will be largely eliminated. With influenza, of course it is always difficult to say where the individual picked up his infection. The problem, however, of overcoming just this difficulty is at present only beginning to be attacked.

DIAGNOSIS OF BRUCELLOSIS

To the Editor—A patient sick for a year is tired and worn out but has no pain oraches. There is no loss of weight. The temperature begins to rise about 1 p.m. and reaches its highest point (from 103.6 to 104 F) about 9 p.m. A frothy mucilaginous material is coughed up at this time. On two occasions the patient has coughed up blood. He is not conscious of the high temperature. With the drop in temperature he has drenching sweat. Physical examination reveals nothing abnormal except enlargement of the liver and spleen. The lungs and gastrointestinal tract appear normal on x-ray examination and tests of the blood are negative for bacteria; there is secondary anemia. Is this undulant fever? The blood does not show it. If it is undulant fever, what line of treatment is advised? What diseases would give a patient these symptoms? WILLIAM L. COWLES, M.D. Shawmut, Ala.

ANSWER—The diagnosis cannot be made from the data given. Some of the diseases which might be considered in the differential diagnosis are tuberculosis, chronic bronchitis or bronchiectasis, hepatic cirrhosis with splenomegaly, chronic malaria, pyelitis or pyelonephritis, lymphoblastoma, subacute bacterial endocarditis and undulant fever.

Repeatedly negative reactions to agglutination tests or negative blood cultures do not entirely eliminate the possibility of brucellosis (undulant fever). The intradermal test utilizing heat-killed or formaldehyde-killed *Brucella* organisms, or the use as an antigen of the standardized *Brucella* nucleoprotein in suspensions (brucin) developed by Huddleson is of value in identifying persons who have acquired cutaneous sensitiveness after the invasion of the tissues by living *Brucella* organisms. The *Brucella* melitensis vaccine (N.N.R.) may be used for the cutaneous test; the vaccine is available through the usual trade sources. This test is of value in the diagnosis of brucellosis particularly in persons (about 5 per cent) in whom no agglutins for *Brucella* are found in the blood serum after repeated testing and in instances in which *Brucella* cannot be grown on culture of the blood, urine or stools. The cutaneous test is also of value in cases in which the agglutination reaction is doubtfully positive in low titer (from 1:10 to 1:100). In interpreting the results of the endermic reaction one must

consider the fact that presumably normal persons may acquire cutaneous hypersensitiveness without symptoms of illness as the result of previous subclinical (asymptomatic) infection with *Brucella*. Cutaneous sensitiveness may also remain after recovery from brucellosis. Thus, a person who has cutaneous hypersensitiveness to *Brucella* antigen may be suffering from some other disease at the time the test is made. A positive reaction to a cutaneous test may be merely the result of asymptomatic or symptomatic brucellosis acquired some months or years previously.

The opsonocytaphagic test of Huddleson (*Am J Pub Health* 23:917 [Sept] 1933) appears to be of considerable value in determining the immunity status of persons who acquire a positive reaction to the cutaneous test. The method involves the measuring of the phagocytic power of the polymorphonuclear leukocytes in an opsonocytaphagic system. The absence of marked phagocytic activity of the polymorphonuclear leukocytes in a patient with a positive reaction to the cutaneous test is believed to indicate active infection due to *Brucella* organisms and a lack of immunity. The presence of marked phagocytic activity would indicate either a developing or an established immunity. If marked phagocytic activity and a positive reaction to the cutaneous test are demonstrated in a patient with fever, it is likely that the fever is due to some disease other than brucellosis. Keller, Pharris and Gaub (*THE JOURNAL*, Oct 24 1936 p 1369) reported favorably on the practicability of the opsonocytaphagic test. In interpreting the results of any of the tests for brucellosis one must give due regard to the clinical symptomatology. If repeated agglutination tests give negative results and if the reaction to the intradermal test is negative, it is unlikely that the patient has or has had brucellosis.

EPILEPSY

To the Editor—A white woman aged 21 in good health had an attack of loss of consciousness. There were four subsequent attacks over a period of eighteen months. An accurate description was not obtained but there was a sudden loss of consciousness lasting only a few minutes with no premonitory signs there was no convulsion but the right arm was held rigid. The stupor was profound on one occasion she injured herself severely and painfully but did not regain consciousness until several minutes later. She is sweet and intelligent there being no evidence of character or mental deterioration. She had been struck in the head by a golf ball with no loss of consciousness several years before the first attack. After the last attack neurologic examination complete ophthalmologic blood spinal fluid and encephalographic examinations were all declared negative by a prominent neurologist. The menses are very profuse last from five to seven days and occur every four to seven weeks. The history otherwise is negative except that a cousin may have epilepsy this is not certain. There have been no attacks for fourteen months during which time the patient has been taking phenobarbital calomel and epsom salt every two to three weeks and is on restricted fluid and a low salt diet. The problem of marriage has now arisen and I should like the following questions answered. Is a diagnosis of epilepsy reasonable? What is the possibility of more attacks? What is the possibility of any children having epilepsy? Might they have a severe type or would it be the same as the mother's? As more than a year has elapsed since the last attack need the prospective husband be told of the condition of the patient? Would anything be gained by waiting a year or more to see whether there will be more attacks?

MD New York

ANSWER—The diagnosis of the convulsive state (epilepsy) depends entirely on the history regarding foaming at the mouth biting of the tongue incontinence of urine and feces, premonitory symptoms and somnolence after the seizure. The rigidity of the right arm strongly suggests the tonic element of a convulsion. If there are no other causes of paroxysmal attacks of profound unconsciousness found, it is likely that the patient has epilepsy. She should be reexamined every four to six months to determine the presence of objective organic signs and symptoms. If she has epilepsy and is not given sufficient anticonvulsant medication, she may have more attacks. Epilepsy is not considered to be actually hereditary but there are many cases on record wherein an epilepsy in a child was associated with epilepsy in either one or both parents. For that reason patients with this condition are advised to continue treatment for a period of from three to five years following the last attack. In this way the pattern or habit of the convulsive state may be sufficiently depressed so as not to recur. All patients with epilepsy in the eligible age for matrimony should be absolutely warned of the possibility of having epileptic children. These patients before having any children, should have no attacks of any kind for a period of three years. It cannot be too strongly urged that any epileptic patient should not countenance matrimony unless the future mate is informed of the condition. If this is not done more trouble than the epilepsy may arise later.

MALIGNANT HYPERTENSION

To the Editor—I have under my care a patient with what has been diagnosed as malignant hypertension. He has been treated for the past two years for what was supposed to have been sinus headaches following tonsillectomy. The headaches were severe and occurred at increasingly frequent intervals. When he reported to me in the course of a routine physical examination the blood pressure was found to be 186 systolic 110 diastolic. An x-ray examination of the sinuses revealed that there was no evidence of a disease condition in the right frontal sinus that would account for the headaches. They generally come on early in the morning or early afternoon and are intense starting first over the left eye and gradually involving the entire left side of the head. The headaches have lasted for as long as thirty six hours. Blood pressure taken during the intensity of one of the attacks was 240/140. Accordingly he was sent to the hospital for a complete physical examination. X-ray examination of the head was negative. There was nothing suggestive about the remaining teeth. The heart showed moderate enlargement to the left. The vessels of the lower part of the legs showed some thickening and calcification. A metabolism test was within normal limits. The prostate was somewhat enlarged but not pathologic. Kidney function and routine tests were normal except for an occasional hyaline cast and a transient trace of albumin. Electrocardiographic tracings showed nothing remarkable. The blood pressure varied but while the patient was in the hospital under treatment averaged about 180/190 systolic and 110/120 diastolic. The patient is 46 years old weighs about 165 pounds (75 Kg.) having lost 20 pounds (9 Kg.) by diet does not drink or smoke has a florid complexion and the vessels of the temporal region are tortuous and dilated. During an attack this condition is marked and there is a marked cyanosis. There is a soft systolic murmur at the aortic valve transmitted into the neck present only during attacks. The Kahn test is negative. The family history indicates only that his mother died at the age of 60 of apoplexy. His past history is essentially negative. He has been in the U S naval service for twenty six years and yearly physical examinations indicate that his present condition has existed for only about a year. Previous yearly blood pressure readings have not been over 132/96. He is active and until his daily routine was curtailed played golf, hunted and enjoyed outdoor activities. If I am correct in my diagnosis having tried to rule out all sources of focal infection I should like to have your advice as to whether or not you consider this case to be one that would be amenable to operative intervention with the sympathetic nerve supply. Recent literature indicates that certain beneficial results are being obtained along these lines and I should like to give my patient the benefit of the best accepted treatment. At present he is much improved so far as the headaches are concerned and although the systolic pressure now reads between 160 and 170 the diastolic pressure rarely goes below 110. I might add that his eyeground examination has showed very slight involvement.

MC Virginia

ANSWER—The family history suggests that the mother also had hypertension. This is a common observation and has no significance with regard to possible surgical intervention. Numerous surgical procedures have been advocated for the relief of this condition, probably the most successful being resection of the greater lesser and least splanchnic nerves. This operation has been performed on more than 250 patients in one clinic, with more than half of the patients receiving marked improvement symptomatically and with maintained drops in systolic blood pressure of 50 points or more. Fifteen per cent are classified as tentatively cured as they have had maintained normal pressure of at least one year postoperatively and all evidence of renal and ocular damage has disappeared. About 75 per cent have symptomatic relief even though the blood pressure is not lowered. These results are more favorable than have been reported following any purely medical regimen. Therefore, operation is probably indicated in this case. The contraindications to splanchnicectomy are age over 50 a decompensated heart and a nonprotein nitrogen in the blood over 45. If these contraindications are not present, the patient would seem to have better than a 50 per cent chance of showing gratifying improvement.

CHRONIC ULCERATIVE COLITIS

To the Editor—The type of colitis in this case is due to an organism called *Bargen's organism*. This type of colitis is amenable to treatment but it is sometimes complicated by a thrombophlebitis of the lower extremities. At the present time this case shows some evidence of inflammation of the veins in the left lower extremity. The condition at present shows some improvement over yesterday. It will be appreciated if you will send me any information you have on this condition both as to the causative organism and the complication mentioned.

STANLEY M GATES, MD Monticello Ark

ANSWER—Chronic ulcerative colitis (colitis gravis) is an infectious disease of the large intestine. Some observers believe that the invading organism is a diplostreptococcus. Such an organism can be frequently isolated from the rectal lesions or the patient's rectal discharges.

Part of the treatment has included the administration of some form of antigenic substance prepared from this type of organism. Further than that the condition should be treated as any severe, destructive infection. Many symptomatic measures may come into play. A generous high calory high protein type of diet as much rest of the bowel as possible,

and other measures of general upbuilding are indicated. A series of small blood transfusions are often helpful. Although rare, the occurrence of thrombophlebitis and even arterial occlusion has been known to occur as a complication of this condition.

BILATERAL ATROPHY OF OPTIC NERVES

To the Editor—I have a patient who is 45 years old and has been blind for five years from bilateral atrophy. Examination of the eyes reveals no irregularity of the pupils; also there is no segmented paresis. The pupils respond to light and in accommodation. All reflexes are good except the knee reflexes which are deep but respond normally. He is rather large or heavy weighs about 210 pounds (95 kg) and is 5 feet 6 inches (168 cm) tall. Examination of his heart with x-rays and the electrocardiograph shows it normal. He has no aches, pains, rheumatic trouble, headache or gastric disturbance. Romberg's sign and all other symptoms are negative. His blindness came on gradually; in fact one eye was blind before he knew anything was wrong with him. He says he never has had any syphilitic lesions and cannot find any evidence of such infection; there is no scar on any part of his person. He has been a rather hard drinker just occasionally not a persistent drinker. He went out with some of the boys but did not drink regularly—just for a night. What is your opinion as to the cause of the optic atrophy? An early reply would be appreciated.

M D, Arkansas

ANSWER—The information included in the question is wholly inadequate to make possible a specific answer. However, it is probable that certain leads may be given that may make it possible to determine a cause for the condition.

The fact that the patient has been blind for five years and yet the pupils respond both to light and in accommodation is most unusual. Cases such as this have been reported and a review of the literature may be found in an article by S. R. Gifford and L. L. Mayer entitled "Retained Pupillary Reactions with No Perception to Light" (*Arch. Ophthalmol.* 6:70 [July] 1931).

Presupposing that the patient still has light perception, a visual field study is definitely indicated to rule out a possibility of interference with higher optic centers and the optic radiations. The fact that blindness came on gradually with one eye becoming blind before the other might indicate a lesion at the chiasm which because of its irregular growth involved one optic nerve before the other. Alcoholic amblyopia is usually seen in persons who are continuous drinkers in that they imbibe alcohol each day over long periods although the daily quantity may be small in amount. Atrophy of the optic nerve due to methyl alcohol poisoning is usually acute but there are so many complicating symptoms that a careful history would undoubtedly decide this factor. Syphilis of the nervous system with optic atrophy and a negative blood Wassermann reaction may be revealed on spinal puncture.

If all these measures are carried out it would seem reasonable to suppose that a definite diagnosis might be made.

RELATION OF TRAUMA TO PEPTIC ULCER

To the Editor—A patient suffering from an old (two years) peptic ulcer had just finished lifting and carrying about forty crates of apples to a truck when he suddenly felt faint and weak and had to be hospitalized for acute duodenal hemorrhage (the site of the ulcer). Can these repeated hernias involved in lifting the crates be responsible for the hemorrhage by direct repeated trauma against the abdominal wall or by the repeated increase and decrease in arterial or venous pressures involved in lifting heavy objects acting on a blood vessel already damaged by the ulcerous process? The last question is based on the idea of those hypertensive patients with arteriosclerotic (damaged) cerebral vessels who suffer from cerebral insult—hemorrhage—incidental to straining at stool. I would appreciate a list of references in the literature concerning only the possible relationship of trauma to a peptic ulcer with attendant hemorrhage.

HENRY ROSNER, M.D., Brooklyn

ANSWER—The relation of trauma to hemorrhage or acute perforation of a peptic ulcer known to be present, as well as to the genesis of the ulcer itself, has been the subject of much controversy as well as of great interest to forensic and industrial medicine. Clinicians of large experience in the field of gastro-intestinal diseases are convinced and have ample proof that hemorrhage may be induced by sustained or unusual exertion particularly severe exertion involving the abdominal muscles as in this case. Other known causes are violent abdominal massage and alcoholic sprees, especially the latter. Even sustained mental activity such as a lawyer may be subject to during an involved trial has been known to give rise to repeated hemorrhage in the same individual.

The mechanism involved is a moot point. Sudden rise in arterial or venous pressure in the splanchnic vessels marked though transient rise in intragastric or intraduodenal pressure and the great shearing strain on the movable parts of the bowel that adjoin fixed ones have been advanced as the factors underlying the hemorrhage. External nonpenetrating forms of trauma may cause laceration of the gastric mucous mem-

brane of variable extent giving rise to hemorrhage even in the absence of ulceration. So far experimental research has not contributed much to a better understanding of the factors involved. The literature on the subject is scanty and tends to minimize the importance of external trauma in the light of present knowledge.

CHRONIC ULCER OF LEG

To the Editor—This condition while quite common is seldom encountered by the average practitioner. A woman aged 51 weighing 200 pounds (91 kg) height 5 feet 7 inches (170 cm) had phlegmasia alba dolens sixteen years ago, ten days after the birth of her first child. Pain began in the left inguinal region and extended rapidly to the foot at which point most of the inflammatory process was expended in red swelling terminating in exfoliation of the plantar cutis of the foot. Resolution left the skin about the ankle indurated; the scar tissue about the nerves and blood vessels adhered to the tibia causing pain. Since then this surface has been ulcerated from time to time healing with difficulty. Eight months ago a physician injected this scarred tissue with something that caused two necrotic ulcers at the point of injection which refused to heal. At this time active inflammation extended to the knee with a temperature of 105 F. The patient remained in bed for about thirty days. At present her general health is normal and she walks about on the leg even with pain which is not accelerated by exercise. The ulcers refuse to heal. The urine is normal (at times there is a trace of sugar). I am doing little in the way of treatment. A hot electric pad is used to keep the leg warm at night. Can you suggest something?

M D, Texas

ANSWER—The condition described by the correspondent is one of the most serious complications of chronic venous insufficiency that may follow femoral thrombophlebitis. The chronic cellulitis and fibrosis that result from this condition make the ulcers that may occur in such an area extremely resistant to treatment. In the particular case described it would be best to have the patient at rest in bed with the extremity elevated. If infection is present in the ulcer, this should be combated with the application of continuous packs of saturated solution of boric acid or a dilute solution of potassium permanganate (1:10,000). When there is a minimal evidence of infection some of the epithelial stimulants may be used. Of these the direct application of the leaf of the plant aloe vera or a dilution of thioglycerol is most satisfactory.

Skin pinch grafts may be successful. In some instances the evidence of the healing of these ulcers is so slight after the best of medical treatment that it may be wise to consider excision of the entire area and the covering of it with a full thickness skin graft. In other instances the patient will need to submit to the disability of the ulceration or, in extreme cases, amputation may be considered. If the ulcer can be healed it is necessary for the patient to wear a type of support that prevents venous stagnation, such as a pure rubber roller bandage, 3 inches wide and 15 feet long.

BILATERAL FOOT STRAIN FROM SHORT ACHILLES TENDON

To the Editor—A young woman suffers from a low heel arch apparently due to bilateral short achilles tendon. I have had the heels of her walking and gold shoes built up to 1 3/4 inches but the result has been that the shoes are now too heavy and since the shoes were not constructed for such high heels the longitudinal arch is not supported and the weight is thrown forward to the transverse plantar arch. Will you please tell me whether it will be necessary to have special shoes built or the name of manufacturers of such shoes with high heels which can be recommended. As this is only a trial to relieve the backache I hesitate to advise a special shoe being made because of the expense. Following the outline given by Mennell in his book on backache I have demonstrated that there is no strain or arthritis or fibrotic deposits present; it is a postural strain. The weight is normal. Any suggestions as to other treatment will be appreciated.

M D, G. C.

ANSWER—This patient apparently has a bilateral foot strain secondary to a short achilles tendon. It is desirable that the patient control her weight so as to relieve pressure on both feet. Rigid shank shoes, with moderate height Cuban type heels are the most satisfactory. These might be reinforced by longitudinal felt pads supporting the longitudinal arches. Such fitting should give much relief. In order to attack the basic etiologic factors it is necessary that the patient start calf stretching exercises and persist with them over a long period. This may be accomplished by having the patient start

in a slightly pigeon toed position, with the weight carried on the outer sides of the feet, and the toes flexed to the floor. The patient then leans forward without bending the knees or lifting the heels from the floor. If this is done properly the patient will experience a stretching sensation on both sides of the popliteal spaces. In order to accomplish the lengthening of the calf group, especially in an adult it is necessary that these exercises be carried out over a long period.

In some selected cases this may be accomplished by the lengthening of the achilles tendon. Although this surgical procedure is not severe the disability and awkwardness of gait may persist for several months after operation.

The use of arch supports may give temporary relief but are not effective in relieving the basic pathological condition. During recent years, many shoe manufacturers have developed perfectly satisfactory rigid shank shoes and in general these may be found as efficient as shoes made to individual measure.

TREATMENT OF SYPHILIS

To the Editor—A man aged 27 in excellent health contracted syphilis in September 1936 at which time I first saw him. He had a primary sore. Darkfield examination revealed the spirochete and the Wassermann reaction was four plus. Active treatment was immediately started. Up to now he has received fourteen injections of neorarsphenamine (0.6 Gm) and seventeen intramuscular injections of a bismuth compound. The primary sore healed within two weeks. No secondary lesions ever developed. The patient is exceptionally cooperative and intends to receive continuous treatment until January 1938. Three Wassermann tests taken at intervals have been negative. He will be married this spring. What is the likelihood for transmitting his infection to his wife and to his offspring? Provided the foregoing program is followed what additional precautions are necessary? MD New York

ANSWER—The patient with syphilis in the seropositive stage needs somewhat more treatment than a patient with syphilis in the seronegative stage. He should have at least forty injections of an arsphenamine and the same number of injections of a bismuth compound in alternating courses of continuous treatment. Distinctly better results have been obtained in cases in which no vacations are allowed that is, if no intolerance to treatment develops. This amount of treatment should be administered even with the negative serologic reports. There is little likelihood of infecting his wife with the amount of treatment before his marriage. They should avoid having children until the course is completed a negative spinal fluid is obtained and negative serologic reaction and absence of clinical manifestations for two years at least thereafter. Both husband and wife should of course be checked serologically and by physical examination from time to time both during and after treatment.

SUDDEN DEATH IN INFANT

To the Editor—I had a sudden death of an infant (18 months old) a few days ago which has me worried from a diagnostic standpoint. When first seen at 9 a. m. the infant had a temperature of 105 F with no abnormal lung conditions. The throat as well as the ears was normal. There was no stiffness or other indications of meningeal involvement. The mother says she only noticed that he was sick about 6 a. m. of the same day. I reduced the fever by cold bathing and acetylsalicylic acid. When seen at 5 p. m. the same day the temperature was 102 F but there were moist rales scattered over both lungs. The pulse was of good volume and about 100. I was called hurriedly at about midnight and found the child dead on arrival. The body was covered with purpuric spots from pea size to about that of a five cent piece. I would appreciate your opinion. MD Texas

ANSWER—There can be no doubt that it concerned some form of acute infection, probably with general bacteria. It would have required bacteriologic examination of the blood to determine the exact nature of the infection.

ALDRICH DYE MIXTURE FOR BURNS

To the Editor—Based on an opinion expressed by Dr Aldrich on the treatment of burns with a compound of aniline dyes (*Maine M J* 28 5 [Jan 1 1937] your advice to the inquiry of Dr Cantwell as published in *The Journal* September 4 p 813 is incorrect. Aldrich states in his latest article. In the two years following the introduction of gentian violet into Johns Hopkins the mortality dropped from 42% to 13%. However gentian violet was not the ideal antiseptic and contamination by gram negatives was a constant annoyance. The combination now employed by Dr Aldrich is acriviolet and brilliant green which he regards as the most powerful antiseptic against the gram positives that will not injure living cells. The solution employed is 1:1000 aqueous solution which has a high phenol coefficient against all the pyogenic organisms. Aldrich frankly states that this combination is not the final answer in the treatment of burns but he emphatically says that the new dye is as superior to gentian violet as gentian violet is to tannic acid.

Book Notices

The Patient and the Weather By William F Petersen M D With the assistance of Margaret E Milliken S M Volume IV Part I Organic Disease Cardio Vascular Renal Disease Including a Chapter on Experimental Endocarditis By Alexander J Vedzel M D Associate Professor in the Department of Pathology Bacteriology and Public Health University of Illinois College of Medicine Chicago Cloth Price \$10 Pp 663 with 443 illustrations Ann Arbor Michigan Edwards Brothers Inc 1937

The present volume is only part I of the fourth volume of a complete set. How long it will be until this masterpiece of research has been completed, one can hardly tell. Single volumes and parts of volumes have been appearing from time to time for several years, and the end is by no means in sight. Volume II, volume III and part of volume I have already been reviewed in these pages, and a small picture of what the writer is trying to do has been presented. The vast amount of material collected by Petersen and his assistants can scarcely be expressed in words. In fact, this book is the type of thing which one is accustomed to find coming from European authors who, it must be admitted, have manifested little of the originality or of the clearness of thought that the present author has and match him only in quantity and in thoroughness. The influence of weather on human beings and on their bodily ailments has been ignored largely because of no obvious relationship but the presence of some such relationship is not beyond the acquaintance of even the layman. The soldier's old wound which pains him, the paroxysms of asthma that occur in certain times of the year regardless of pollen, and other interrelationships between weather and physiologic dynamics have been casually recognized but never understood.

It is not yet clear perhaps whether Petersen entirely understands this relationship, but he does have a theory which he is carrying consistently through all these massive volumes to point out that there are certain complexes related to high and low pressure which are accompanied by a certain chemical change. It would be fallacious to try to discuss this theory in brief any further than to make this single, simple statement. Polar fronts, temperature variations and other climatic conditions all seem to enter into the picture in an extremely complicated fashion. The earlier volumes which appeared seem to be a rather vague and yet earnest attempt to correlate such a broad external as the weather with vague, indefinite entities such as types of psychoses and neurologic conditions. Some evidence certainly was presented for an interrelationship. With continued writing and continued investigation the interrelationship is now becoming much clearer, and it must be admitted that the tenseness manifested by Petersen in the earlier volumes has now disappeared and some whimsy and other evidences of a feeling of greater security in his research are now manifested.

The earliest parts of the book deal with well known cases such as the death of Melvin Traylor, the president of the First National Bank in Chicago, and the Maguire case, the girl who for so many years was in a semicomatose condition. The fluctuations in these cases are shown to have a definite relationship with changes in climatic conditions. Numerous similar or closely related cases are culled from the literature and from the practice of physicians associated with the author to bring out his point further. And in this first part of the book the small charts used by Petersen to show the relationship of the various fluctuations in the patient's physical condition with the weather, being simpler than those in the last part and in previous volumes seem more dramatically and more emphatically to bring out his points. He concludes this section with a short discussion of what Aesculapius would say today if he were confronted with such an idea as Wilson's laryngeal constipation. Regarding the asthmatic condition which Wilson interpreted as being due to Freudian complex material but which the present author demonstrates in rather an interesting fashion to have a more clear-cut relationship with weather conditions he shows that when the most serious asthmatic attack occurred there was an extremely bad dust storm in the Chicago area. This discussion, which would be of interest to any earnest scientist, takes nearly a fourth of the contents of the entire volume the remainder being occupied with careful case studies of cardiorenal disease, showing the relationship of paroxysms

and changes in the cardiorenal function with changes in the weather. The volume ends with a discussion of experimental endocarditis produced in animals by Alexander J. Nedzel, who shows that there is a definite relationship between the author's "pressor" complexes and cardiac function. There are some beautiful micropathologic plates in this part, and the whole volume is, as are all the previous volumes, heavily interlarded with complicated graphs showing fluctuations in all the bodily functions in various cases during periods of climatic change.

Petersen shows why there is such an increase in acute cardiac and respiratory disorders in the month of March. The discussion here, which is a bit of cumulative evidence that fits in with the rest of the discussions in the volume, emphasizes Petersen's point that the unstable individual with low capillary blood pressure and a tendency toward acidity and other negative chemical changes is more susceptible to meteorological fluctuations. On investigating one's own attitude toward the subject, one would be inclined to agree with Petersen's results in general, but an evaluation of the immense amount of material which this huge volume encompasses had best be left with the investigator and reader himself and, perhaps, to time. The book cannot be recommended as light reading for an evening. It is unquestionably deep. It requires background both in meteorology and in medicine and pathology. But judging from important European literature, Petersen's work is undoubtedly the harbinger of a next major step in both theoretical and medical research.

La spondylolyse et ses conséquences. Spondylolisthésis—scoliose lit. thésique. Etude radiologique—clinique—médico légale. Par Pierre Glorieux et Carle Roederer. Paper. Price 60 francs. Pp 207 with 138 illustrations. Paris: Masson & Cie 1937.

This monograph is of manifest value as a roentgenologic study of lesions of the vertebral column. Spondylolysis is defined as a dissolution of continuity of the posterior vertebral arch between the superior and inferior articular facets. The "lysis" may traverse the base of the arch as it approaches the facet, the authors call this the intra-articular isthmus, often involved in spina bifida. In a comprehensive review of the literature, important developments are noted. The Eskimo race is apparently exempt from low back lesions. Willis and Schmorl microscopically found inclusions of cartilaginous islands at the base of the posterior arches in cases in which premature arrest of enchondral ossification led to incomplete bony fusion. The causes considered adequate to produce spondylolysis are congenital, traumatic, mechanostatic stress, degenerative processes, the osteochondritides, destructive bone diseases and tumors. Spondylolysis is a radiologic diagnosis. In the three-quarter oblique view an oval, "tear drop" shadow is noted at the isthmus, occasionally a V shaped defect is found in the anteroposterior view.

Spondylolisthesis is a major complication of spondylolysis. Prespondylolisthesis as described by Whitman is an undesirable term and is really a form of spondylolysis. In the roentgenogram the vertebra subjacent to the slipping one often shows spurs and the fifth lumbar vertebra at the anterior borders, especially inferiorly, has increased calcification. A good radiologic study includes an anteroposterior stereoscopic film in indistinct cases, a lateral film, an oblique film of from 45 to 70 degrees, which is usually best for demonstrating the posterior arch, and a three-quarters view to bring out the isthmus. The authors feel that early cases are best diagnosed in the anteroposterior film. Five diagnostic points are emphasized: 1. The spinous process and the arch of the involved vertebra are elevated, approximating the spinous process above the lateral view is negative. 2. The upper and lower vertebral borders are closer together owing to narrowing of the height of the involved body. 3. The projection of a bony line connecting the upper angle of the spinous process (across the posterior facies) with the base of the facet normally ends in the roentgenogram just below the pedicle, in spondylolysis it continues transversely across the body of the pedicle. 4. A gap or defect is visible even in the absence of slipping supporting the congenital theory of spondylolysis. 5. Ullmann's line in the lateral view may be negative and yet fail to rule out a moderate slipping.

Scoliosis is considered in this work only in its relation to spondylolysis. It may result even with a slight unilateral lesion.

It is often present in bilateral defects, chiefly because of the asymmetry of the lesions. The illustrations throughout the book are excellent. Each reproduction of a roentgenogram is accompanied by a pen and ink diagram. The detailed relationships are too complicated for review but are worthy of study by those interested in this field. The section on experimental radiology is exceptionally good and the authors are able to demonstrate the slightest bony defects. The sections on the medicolegal aspects and obstetric complications of spondylolysis are interesting but do not add materially to the value of the monograph.

Untersuchung über die Todesfälle an Krebs in den grossen Städten der Welt. Von Wilhelm Bohmert. Extrait du Bulletin de l'Institut International de Statistique. Tome XXX. Paper. Price 150 florins. Pp 71. The Hague 1937.

The author, commissioned by the International Institute of Statistics, has undertaken an extensive survey on the incidence of cancer in the large cities of the world, usually those of more than 500,000 inhabitants. It includes the United States and Canada, Argentina, Chile, Peru, British India, Japan, Egypt, the South African Union, Australia, New Zealand, and all the European countries except Yugoslavia, Turkey and Russia. The statistics cover the general incidence of cancer in five year age groups, separated according to sex. Only cancer of the oral cavity, the respiratory tract, the intestinal tract, the breast and the uterus are discussed separately. It is interesting to note the uniform age distribution of cancer in such heterogeneous populations as those in the United States and Japan. Also a comparison of the cancer deaths of the same population in different years shows a striking uniformity. The comparison of the death rate in the age groups between 40 and 60 years as it occurred in 1920 and in 1930 shows no regular trend. Although most cities show a relative decrease of the relative cancer mortality (based on 10,000 living members of the population between the ages of 40 and 60) some also show an increase. A few interesting figures are shown in the discussion of the distribution of cancer of the various organs in different populations. Japan shows by far the highest relative incidence of cancer of the digestive tract, followed by Norway and Czechoslovakia (in males 88.4 per cent of all cancers). In the Anglo-Saxon countries the incidence of cancer of the digestive tract is considerably lower (between 55 and 60 per cent). The reverse is true of the incidence of cancer of the breast: the highest incidence is in the Anglo-Saxon countries (from 17 to 27 per cent) and the lowest incidence in Japan (37 per cent in Tokyo). This study does not lend itself to a detailed review and only a few of the striking points could be stressed. It gives a complete tabulation, which should be studied in detail by those interested. The material is presented extensively, enabling one to compute some figures not discussed by the author. The general trend is critical, with emphasis on the possible pitfalls and the limits of conclusions which can be drawn from this material.

Electrocardiography. By Chauncey C. Maher, B.S., M.D., Assistant Professor of Medicine, Northwestern University and the Montgomery Ward Medical Clinics, Chicago. Second edition. Cloth. Price \$4. Pp 254 with 50 illustrations. Baltimore: William Wood & Company, 1937.

This edition is a vast improvement over the first, and most of the glaring errors present in the previous edition have been removed. The book is still unnecessarily involved for the purpose for which the author states it is intended. Further improvements would come from the use of (1) a less clumsy style, (2) a more distinct separation from the text of the electrocardiograms and diagrams so as to make it less difficult to follow the text, and (3) the use of original electrocardiograms instead of retracings, which give one a feeling of unreality and show inaccuracies in several places. A few of the errors present may be mentioned. On page 24 the author fails to note that there is a cylindrical lens in front of the camera aperture. On page 38 he fails to point out that 10 mm is equal to 1 millivolt. The auricular T wave mentioned on page 40 is not visible in the electrocardiogram (3) referred to. Electrocardiogram 11 would be considered abnormal by most authorities. Upper nodal rhythm is called auricular ectopic rhythm on page 71, whereas in electrocardiogram 17, illustrating this point, the correct diagnosis is made. The com-

plete auriculoventricular block present in electrocardiogram 23 is not mentioned, and the probable presence of digitalis intoxication is overlooked. The use of the terms supranodal and infra-nodal on page 88 is inaccurate. The premature contraction in electrocardiogram 26 is auricular and not nodal. Figure XXII is inaccurate, since it shows an RR interval after the second nodal escape longer than the RR interval between nodal beats. The P waves of the diagram in figure XXIII are incorrectly drawn. Electrocardiogram 30 is a poor example of wandering pacemaker. On page 108 the author fails to mention that ventricular fibrillation is sometimes a transitory phenomenon. The prolongation of QRS duration in electrocardiogram 37 is not mentioned. The significance given to slurring of QRS in indicating intraventricular block is misleading. The diagnosis of bundle branch block in electrocardiogram 40 would not be generally accepted. There is no evidence for the statement made on page 129 that right bundle branch block is more serious than left. The sinus arrhythmia in electrocardiogram 46 is overlooked. The diagnosis of left wall infarction on the basis of electrocardiogram 61 alone is unjustified.

Errors such as these give the impression that the text was carelessly written. In view of the many splendid books now available on electrocardiography, there is nothing to commend this one.

Über Veränderungen des Elektrokardiogramms bei orthostatischer Zirkulationsstörung Von Sven Åkesson Med Lic. Gott. Nation. Inauguraldissertation Aus dem Physiologischen Institut der Universität Uppsala. Aus Upsala Lakareforenings Förhandlingar N F Bd VII. Haft 5 6. Paper. Pp 383 499 with illustrations. Uppsala. Almqvist & Wiksells Boktryckeri A B 1936.

This monograph presents the results of a study of the electrocardiographic changes in persons with orthostatic circulatory insufficiency. Forty five such patients were studied and compared with 200 normal adults used as controls. The correlations were carried out on a mathematical statistical basis. In orthostatic circulatory insufficiency, the acceleration of the heart, the decrease in pulse pressure, the rise in diastolic and the fall in systolic pressures are greater than normal on standing up and symptoms of cerebral anemia are more frequent. The author concludes that there is a greater frequency of flattening and inversion of the T wave in leads 2 and 3 on assuming the upright position when there is orthostatic circulatory insufficiency than when this condition is absent. In addition to the T wave change, the ST becomes depressed. Immersion of two patients under water to counteract the effect of hydrostatic pressure prevented the occurrence of the electrocardiographic signs and other circulatory changes previously noted in these patients on assuming the upright position. In three of the seven cases in which fainting occurred on standing, the electrocardiograms showed evidence of vagus stimulation of the heart in the form of slowing and block. The author concludes that the circulatory changes in the heart responsible for the electrocardiographic alterations are the result of oxygen lack caused by the development of a relatively inadequate coronary circulation in the upright position. The monograph includes a good survey of the recent literature dealing with angina pectoris and coronary flow.

Trauma and Disease Edited by Leopold Brahm, B.S. M.D. Physician in Charge of Industrial Diseases and Accidents in the Office of the Corporation Counsel of the City of New York, New York City, and Samuel Kahn, B.S. M.D. Medical Examiner in the Bureau of Workmen's Compensation of the Department of Labor, State of New York, New York City. Cloth. Price \$7.50. Pp 613 with 9 illustrations. Philadelphia. Lea & Febiger 1937.

The contributors to this book are well chosen. They include Adair Woodruff, Abbott Crohn de Takats, Ebaugh Benjamin, Goetsch, Joslin Root, Marble, Knox, Kraus, Eloesser, Ottenberg, Pemberton, Pollock, Roberts, Solomon, Steindler, White and Glendy. The subjects discussed include heart disease, peripheral vascular disorders, pulmonary disease, gastrointestinal genito-urinary, obstetric and gynecologic diseases, mental disorders, diseases of the nervous system including neurosyphilis, bone diseases, chronic diseases of the joints, diseases of the spine, neoplasms, diabetes, disturbances of the thyroid glands and septicemia. The book is almost devoid of photographs, diagrams, charts and roentgenograms but is full of interesting theoretical and practical discussions. The pro-

fession should welcome the volume because it bridges the gaps between the clinical practitioner, the research man, the industrial and insurance doctors and the legal profession. Valuable and concise knowledge is provided for the specialist and should lead to better expert testimony and understanding in compensation and insurance problems.

Electrical Signs of Nervous Activity By Joseph Erlanger, Professor of Physiology, Washington University, and Herbert S. Gasser, Director of the Rockefeller Institute for Medical Research. Cloth. Price \$3.00. Pp 221 with 113 illustrations. Philadelphia. University of Pennsylvania Press. London. Oxford University Press. 1937.

This book is a model for conception, content and clarity in scientific exposition. Consisting of several lectures each by the two authors, there is a minimum of duplication and a maximum of factual and theoretical matter of real value to the serious student of the problem of nervous activity. The modern knowledge of the types of fibers in peripheral nerve is traced from its inception. The importance of the cathode ray oscillograph in the analysis of nerve action potentials is brought out, and the various characteristics of nerve fibers are described. The significance of the several phenomena involved in the action potential is discussed in the light of numerous experiments and finally the excitability cycle in peripheral nerve and in the central nervous system is described. The whole book is a detailed statement and review of the authors' original investigations and earlier research, with closely argued logical inductions. It treats of controversial subjects but not in the spirit of controversy. Reference is made to Claude Bernard's remark in his Introduction to the Study of Experimental Medicine that "When two physiologists quarrel, each to maintain his own ideas or theories in the midst of their contradictory arguments only one thing is absolutely certain: that both theories are insufficient and neither of them corresponds to the truth." The authors of this book deal with theories not so much to defend them as to use them for the prosecution of their problems. This is the most valuable book of the last ten years on the physiology of nervous activity.

Das Reizleitungssystem und die Nerven des Säugetierherzens. Eine anatomische, genetische und experimentelle Studie. Von Bernhard Wahlin, Med. Lic. Östg. Inauguraldissertation. Aus dem Histologischen Institut der Universität Uppsala. Paper. Pp 106 with 73 illustrations. Stockholm. Isaac Marcus Boktryckeri Aktiebolag. 1937.

This monograph includes some original work done by the author on the conduction system of the heart. He reports observations on the anatomic distribution of the conduction system in the beef, sheep and pig heart. He emphasizes the presence of the Purkinje system throughout the myocardium except in the upper parts of the septum around the first portion of the bundle branches and near the auriculoventricular groove. He describes in detail the connections of the bundle branches with the Purkinje system and stresses the presence of a Purkinje network in the lower part of the interventricular septum linking the two ventricles. While these observations have been made before they are not generally known. The author has confirmed the presence of an extensive nerve plexus surrounding the conduction system. He studied the development of the conduction system in beef embryos. He found that the auriculoventricular node is differentiated before the common bundle, its branches and the Purkinje net. The node comes from the auricular canal and the rest from the ventricular canal. The bundle branches become apparent histologically after the Purkinje net is fully developed. Nerve fibers are found to arise from both the arterial and the venous mesocardium, the former supplying the auricles and the latter the ventricles. The nerve fibers appear before the conduction system is differentiated. The monograph is concluded with a preliminary report of experiments in which cod liver oil given to two mice caused incomplete and complete degeneration respectively in the bundle of His. This was unaccompanied by nerve fiber destruction and was associated with no auriculoventricular conduction disturbance in the first animal and with a partial auriculoventricular block in the latter. From these data the author concludes that the auriculoventricular conduction is neurogenic and not myogenic. This last conclusion is unjustifiable since the results can be explained satisfactorily on a myogenic basis and it does not fit the mass of evidence now available in support of the myogenic nature of conduction. Myogenic conduction in the

mammal is now considered by most authorities to be a fact and not a theory. Except for the last section, the work presented fits in with and enlarges our knowledge of the development and distribution of the specialized muscular tissue in the mammalian heart, as the author points out clearly. Any one interested in this subject will find the monograph well worth reading.

Children Handicapped by Cerebral Palsy. Psychological Factors in Management. By Elizabeth Evans Lord Ph.D. Psychologist to The Children's Hospital Boston. With a medical explanation by Bronson Crothers M.D. Visiting Physician to The Children's Hospital Boston. Cloth Price \$1.25. Pp. 105 with 9 illustrations. New York Commonwealth Fund London Oxford University Press 1937.

This book discusses the psychologic factors in the management of children with cerebral palsy. It summarizes observations and experience gained over a nine year period during which 300 cases of cerebral palsy were studied. Dr. Crothers' medical explanation of the nature of the problem presented by these children constitutes the first chapter. Treatment by muscle training with special emphasis on the psychologic problems involved, and the prediction of physical efficiency are discussed. The most important sections of the book are those which describe the mental testing program by which the children were studied, and the subsequent discussion of the mental development of the children and their specific educational needs. Dr. Lord shows how it is possible for a skilled psychologist to arrive, through repeated examinations at a reliable estimate of the handicapped child's mental development, in spite of the fact that his physical difficulties obscure the picture and make it impossible to apply the usual tests in the usual manner. The author properly lays the greatest emphasis on adequate prediction of the mental growth and development of the children, since this is essential to the construction of a rational educational program. The unevennesses and irregularities in the mental development of the child suffering cerebral damage are described. Dr. Lord discusses the special problems with which the teacher of the handicapped child is faced. The final chapter deals with the emotional problems created for child and for parent by the presence of physical handicap with particular emphasis on the difficulties created by lack of proper evaluation of the child's potentialities and misguided or mistaken efforts to achieve goals not possible to the child. Dr. Lord has written in simple language and with the greatest of clarity. This is an authentic and important study with which every physician and teacher responsible for care of physically handicapped children should be familiar.

Opuscula selecta Neerlandicorum de arte medica. Fasciculus quartus decimus quem curatores miscellaneorum quae vocantur *Nederlandsch Tijdschrift voor Geneeskunde* collegerunt et ediderunt. Amstelodami Sumptibus Societatis De Medicina tropica. [Selected Dutch Writings on Medical Art. No. 14. Tropical Medicine. On Some Natural and Medical Matters from the Indies. By Gullelmus Piso. Treatise on the Asiatic Leprosy. By Wilhem Ten Rhyne. Treatise About the Most Excellent Herb Tea. By Cornelis Bontekoe.] Cloth. Pp. 465 with illustrations. Amsterdam 1937.

This volume is the fourteenth in the notable series of selected Dutch medical writings published by the *Nederlandsch tijdschrift voor geneeskunde*. It deals with the life and work of three remarkable Dutch physicians in the seventeenth century, Willem Piso, Wilhem Ten Rhyne and Cornelis Bontekoe, parts of whose writings are printed in Dutch and in English, preceded in each case by a biographic introduction and commentary.

Willem Piso, 1611-1678 physician in Amsterdam, served as chief of the medical service in the Dutch colony in Brazil from 1637 to 1644. In 1648 his great work on Brazilian medicine was published "an exceedingly well executed wonderfully illuminated folio volume." In this book are described the uses of ipecacuanha in dysentery and a form of lues, known as 'bubas' or jaws which can be transmitted 'by the slightest touch.' In his introductory sketch of Piso M. A. van Andel concludes that "to Piso the honor is due of having first given clear directions" regarding the use of ipecacuanha as a specific remedy 'for one of the most daunted diseases of his time.'

The first two chapters of Ten Rhyne's Treatise on the Asiatic Leprosy, 1687, are reproduced. These chapters deal with the differences between the kinds of leprosy and with signs and symptoms. In his introduction D. Schoute tells that Wilhem

Ten Rhyne, born in 1649, took his doctor's degree in 1670 sailed for the East Indies in 1673 and served as director of the hospital for leprosy in Batavia.

In his interesting introductory sketch, De Feyfer characterizes Cornelis Bontekoe, 1647-1685, as "an idealist, a problematic and troublesome companion, a spoilsport, his life was continually a source of conflicts, in short he belongs to the schizothymic type." His merit is to have introduced "the general use of tea, coffee and cocoa in the Netherlands and Germany. About 345 pages are occupied with the reproduction of his treatise on tea (1678).

Cataract. Its Preventive and Medical Treatment For Specialists General Practitioners and Students. By A. Edward Davis A.M. M.D. Consultant Ophthalmic Surgeon New York Post Graduate Medical School and Hospital (Columbia University). Cloth Price \$3. Pp. 161. Philadelphia F. A. Davis Company 1937.

The author, after discussing the history and etiology of senile cataract, takes up in order the symptoms of incipient, immature and mature cataracts, and their pathogenesis and spectroscopy. This is all a review and nothing new is contributed. Under treatment he first discusses errors of refraction and dietary treatment. In chapter X, on other methods of nonoperative treatment of cataract, he enumerates the use of various drugs, vitamins, endocrine preparations and lens antigen in which he is most interested and with which he is most concerned. He gives a series of case reports in which he endeavors to prove that with the use of lens antigen the cataract in the second unoperated eye was either arrested or partially absorbed with maintenance or improvement of vision. He cites the experience of other observers who differ with him in their conclusions as well as those who support his views. The book does not contribute anything new to our knowledge of cataracts or their medical treatment and the case reports do not conclusively show either arrest or definite improvement or clearing of lens opacities.

Der Myokardinfarkt. Erkennung, Behandlung und Verhütung. Von Professor Dr. Max Hochrein Oberarzt an der Medizinischen Universitätsklinik Leipzig. Kreislauf Bücherheft. Herausgegeben in Verbindung mit der Deutschen Gesellschaft für Kreislaufforschung. Band I. Paper. Price 12.50 marks. 1 p. 196 with 52 illustrations. Dresden & Leipzig Theodor Steinkopff 1937.

In this monograph the author has correlated the recent developments of the subject of myocardial infarction. This condition, as the author points out in his introduction, is a leading cause of death and consequently deserves the attention of every practicing physician. After an introduction in which the historical background is surveyed the author summarizes the frequency of infarction in his clinic during the last seven years and correlates it with the reports of other observers. A section on the hemodynamics of the coronary circulation follows, starting with the anatomy of the coronary arteries and including the normal and pathologic physiology, experimental studies on closure of the coronary arteries and the gross morbid morphology and histology of infarction. The rest of the monograph is devoted to the clinical consideration of infarction. This includes the etiology, the clinical picture, the typical symptomatology, the atypical forms of the disease, its usual course, its diagnosis and its prognosis. The treatment and prophylaxis of this disease are dealt with at length. An extensive bibliography is appended. While the author correlates his own observations with those of others this is not done at the sacrifice of simplicity of style. There are, of course, a number of points of view expressed by the author with which American authorities would disagree. The electrocardiograms are not adequate and could for the most part have been omitted. No precordial leads are presented and this aspect is rather lightly dismissed.

Physiology and Pathology of the Heart and Blood Vessels. By John Piesch M.D. L.R.C.P. & S. Professor of Internal Medicine in the University of Berlin. Cloth Price \$5.25. Pp. 188 with 15 illustrations. New York & London Oxford University Press 1937.

This book is a study of the hydraulics of the circulation in health and disease and as such lays no claim to the completeness of a textbook. The author attempts to analyze the normal and pathologic relationships of the various parameters of the circulation wherever these could be treated on a purely physical basis. For this purpose various mathematical formulas have been included and applied wherever possible. The author

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

stresses the "genuineness" of the views presented and hence almost no references are given. The text introduces many new terms, such as specific dilatibility, systolic and diastolic insufficiencies and force limit, in describing well known cardiodynamic events. These terms, while descriptive, are no particular improvement over those more commonly used. In places, especially in the discussion of venous pressure, on which much stress is laid, the choice of words is confusing and the subject would be much clearer through the substitution of charts for words. There are numerous views presented to which many physiologists will take issue, such as that during auricular systole there is a large back thrust of blood into the great veins, that in aortic insufficiency there is neither an increased systolic discharge nor hypertrophy of the left ventricle, and that contraction of cardiac and skeletal muscle does not impose any serious impedance to blood flow through the muscle. Such views appear to arise from the author's expressed idea that "changes in the circulation of a mechanical nature do not need experimental corroboration." In general the organization of material is good and the book is well written, especially the chapters on circulatory insufficiency. However, the whole text could be greatly condensed without sacrifice of clarity. Despite limitations some of which have been mentioned, the book will be well worth reading if the reader will bear in mind that the author emphasizes theoretical deductions rather than experimental observations.

Your Diet and Your Health By Morris Fishbein M.D. Editor The Journal of the American Medical Association. Whittlesey House Health Series. Morris Fishbein M.D. editor. Cloth Price \$2.50 Pp 298 New York and London Whittlesey House McGraw Hill Book Company Inc 1937

This is a most readable book on foods and diet, a book which contains an extraordinary amount of information. It includes discussions of calories, the cost of food, the physiology of appetite and digestion, the components of our diet, the nutritional value of foods in general, food sensitivities, the diet in various disease conditions, and peculiar schools or "systems" of dieting. There is appended a considerable amount of tabular material regarding diets and food values in terms of carbohydrate, protein and fat. There is a suitable index. Practical suggestions are included in every chapter and the book is a useful guide to those who wish to "eat for health." Humorous touches deftly applied render the scientific facts mentally digestible. The book is dedicated to Anna Mantel Fishbein, "whose culinary accomplishments," writes the author, "in the younger years of my married life and whose graduate studies in this field in later years have maintained a constant war between my weight and my appetite."

Technique of Underwater Gymnastics. A Study in Practical Application By Charles Leroy Lowman M.D. F.A.C.S. Chief of Staff and Director of Educational Activities Orthopaedic Hospital Los Angeles California. Susan G. Roen Director of the Physical Therapy Department Orthopaedic Hospital Los Angeles. Ruth Aust B.S. and Helen G. Paul B.S. Sponsored by Los Angeles Orthopaedic Foundation. Cloth Price \$3 Pp 276 with illustrations Los Angeles California American Publications Inc 1937

This book offers a modern basic survey of the history, the theory and the conditions suitable for hydrogymnastics. It includes also four valuable chapters on the use of corrective aquatics, which are especially timely. Practical suggestions on the construction of physical therapeutic pools and their physical equipment as well as administration and departmental arrangement are included. Dr. Lowman successfully employs underwater exercise in certain postoperative cases, in cases of arthritis infections and open wounds fractures and poliomyelitis and in spastic patients. The book will be found instructive by all who deal either directly or indirectly with specific problems of posture or health.

Joint Range Chart to Show the Range of Motion of the Joints of the Extremities Paper Price 25 cents Harrisburg Pennsylvania Medical Society of the State of Pennsylvania [1937]

This pamphlet contains seventeen illustrations, which attempt to simplify terminology with regard to the range and direction of movement of certain joints. The illustrations are not particularly good.

Workmen's Compensation Acts Compensability of Sacro-Iliac Strain—The workman was employed in the warehouse of the National Biscuit Company moving barrels and other articles of merchandise. He stooped to reach a barrel and was seized with a sharp pain in his back and left leg. Temporary total disability resulted. The state industrial commission made an award in favor of the workman, and the company instituted original proceedings in the Supreme Court of Oklahoma to obtain a review of that award.

Under the workmen's compensation act of Oklahoma, an employer is required to pay compensation for disability resulting from an accidental personal injury sustained by an employee when it arises out of and in the course of employment. In the present case the medical testimony was to the effect that the workman suffered a "right sacro-iliac strain and sciatica and was temporarily totally disabled from performing ordinary manual labor." The question presented to the Supreme Court was whether or not under the circumstances the workman sustained an accidental injury within the meaning of the workmen's compensation act. An examination of cases previously decided in Oklahoma, said the court, discloses that where a finding of accidental injury has been sustained there has been evidence to the effect that it was the result of some external cause although there was no trauma or external manifestation of injury. In the present case the court was asked to go a step further and to hold accidental a muscle strain which according to the evidence happened apparently without cause other than the act of stooping over to perform work. In other words, the court was asked to say that an act which required no unusual exertion, which presented no sudden strain on the workman's muscle but in every way was the normal and usual function of his body except for the resulting disorder, should be deemed an accident. If we should so hold, the court continued, we must be prepared to hold that every muscle or nervous strain which an employee sustains and which results in a disability is accidental regardless of any apparent external cause or stimulus producing such condition. So to hold would in effect nullify rather than construe the provisions of the workmen's compensation law. The most that can be said of the workman's evidence, the court concluded, is that he sustained a "muscular strain" for no apparent reason except that he stooped over. To say that it was accidental merely because it was unexpected would be to authorize a judgment based on conjecture, surmise and speculation. Under such circumstances the court concluded that there was no competent evidence before the commission on which to base its findings of accidental injury and that therefore the commission was without jurisdiction to make any award. The award of the commission was vacated for want of any competent evidence to support it—*National Biscuit Company v. Lout (Okla.)*, 65 P. (2d) 497.

Hospitals Hospital Bills Accorded Priority in Payment out of Insolvent Patient's Estate—In North Carolina the debts of a deceased person are classified by law for the purpose of determining the order in which they are to be paid. Claims "for medical services within the twelve months preceding the decease" form a part of the sixth class. All other debts, not included in the preceding six classes are embraced in the seventh class. The defendant was the executor of a decedent who during a portion of the last twelve months of his life was hospitalized in a hospital operated by the plaintiff association. An expense of \$655.60 was incurred for a private room, drugs, special laboratory examinations, use of the operating room, board for graduate nurses and meals for the decedent's wife. The decedent's estate was insufficient to pay all debts. If the plaintiff's claim was allowed priority under class six, as a claim for "medical service," the estate was sufficient to pay it in full. If the claim was properly classified

as included within the seventh class of the decedent's debts, the plaintiff would receive approximately 57 per cent of its claim. The executor refused to accord priority to the claim, and the plaintiff sued. The trial court held that, with the exception of the amounts due for the board for nurses and for the meals furnished the decedent's wife, the claim should be classified for payment as included within the sixth class. Both the plaintiff and the defendant appealed to the Supreme Court of North Carolina.

In speaking of the statutory preference of a debt incurred by a decedent for medical services rendered him within twelve months preceding his death, said the Supreme Court, it was said in *Baker v. Dawson*, 131 N C 227, 42 S E 588:

It must be noted that there is no priority even for medical services rendered the deceased personally unless he dies. In all other cases the physician's bill is like any other debt. If the physician wishes to secure such debts he must exact security or proceed to collect by law. When the patient is in his last illness this might be inconvenient or indecent and as such illness might extend to twelve months the law endeavors to secure for the patient medical attention by giving a legal priority for such services if rendered to the patient within twelve months preceding his decease. But such reason does not apply to services rendered his wife and children as to which the physician has extended credit relying upon the father or husband or landlord himself paying the debt incurred. There are no words extending the meaning to such debts other than personal services to the debtor and the language of the statute is restrictive. — For medical services within twelve months prior to the decease — meaning the decease of the debtor not of his wife, child or tenant. The statute being in derogation of the equity of a pro rata distribution should be strictly construed so as not to confer a priority over other creditors unless clearly called for.

With the principle applied in the Baker case, the Supreme Court of North Carolina expressed itself as in agreement but held that that principle did not require such a restricted construction of the words "medical services" as to exclude from the provisions of the statute services rendered by the plaintiff to the deceased within twelve months preceding his death. These services were rendered on the advice of decedent's physician and were reasonably necessary, because of his illness, for his care and comfort. When the plaintiff admitted the decedent into its hospital, it doubtless felt assured, the court said, that if he recovered from his illness he would pay his hospital bill, and that if he died within twelve months from the date of his admittance it would have a preferred claim for its services on his estate. The words "medical services," as used in the statute, the court said, include all services rendered to the decedent, because of his illness, on the advice of his physician, which were reasonably necessary for his care and comfort, and for his proper treatment by his physicians.

In the opinion of the Supreme Court, the trial court erred in excluding from the provisions of the statute the amount due the plaintiff for board for the graduate nurses who attended the decedent. The evidence showed that it was necessary that these nurses should attend the decedent constantly and it was not only convenient but reasonably necessary for the plaintiff to furnish board for them. The judgment of the trial court, therefore, should have included the item charged for the board of such nurses. Subject to this modification, the judgment of the trial court was affirmed.—*Park View Hospital Ass'n Inc. v. Peoples Bank & Trust Co.* (N C) 189 S E 766.

Narcotics. Invalidity of Nevada Narcotic Drug Act Because of Insufficiency of Title.—Medeiros was charged with the unlawful possession of narcotic drugs in violation of the uniform narcotic drug act of Nevada and was imprisoned pending his trial. He applied to the Supreme Court of Nevada for a writ of habeas corpus, contending that the act was unconstitutional.

The Nevada constitution provides that "each law enacted by the legislature shall embrace but one subject, and matters properly connected therewith, which subject shall be briefly expressed in the title." The title of the narcotic act,

An Act defining and relating to narcotic drugs and to make uniform the law with reference thereto," violated the constitutional requirement, Medeiros contended, because it failed to set forth the subject sought to be legislated on in such a manner as fairly to give notice of the contents of the act. With this contention, the Supreme Court of Nevada agreed. The title of the act declares that the act relates to

narcotic drugs, and defines them, it does not express in what manner it relates to narcotic drugs. It does not indicate that the act prohibits the unlawful possession of such drugs nor does it indicate that the act in any way regulates their use. The state argued that the connection between the provisions of the act making it unlawful to possess narcotic drugs and the title "defining and relating to narcotic drugs" is obvious. This was so, it argued, because it is commonly known that it has been the public policy of the state of Nevada for many years to prohibit the use and possession of narcotic drugs by persons other than physicians, druggists and veterinarians who are limited in their possession and use of these drugs to professional use. On this account, it contended, the members of the legislature and the public could not have been misled by the title as to the subject-matter of the enactment. This argument, answered the Supreme Court, might have some force if the constitutional provision involved provided that the title must impart notice of the subject. But such is not the case. It provides that the subject shall be briefly expressed in its title and no presumption of knowledge will satisfy this command. The second part of the title, "and to make uniform the law with reference thereto," gives no validity to the title. It does not undertake to specify any particular law where the subject may be found, and even if it did, such reference would not satisfy the requirement of the constitution.

The narcotic act was enacted in 1933. The legislature, in 1935, undertook to amend the title. But, said the Supreme Court, if a law so conflicts with the constitution as to be entirely void there is nothing to amend. The action of the legislature, in 1935, therefore could not validate the narcotic act. In the opinion of the Supreme Court the 1933 act was entirely void and Medeiros was ordered released from custody.—*Ex parte Medeiros (Nev.)*, 64 P (2d) 346.

Dental Practice Acts. Complaint Framed in Terms of Statute Valid, Restrictions on Ownership of Dental Offices Upheld.—One Florence Williams was charged with practicing dentistry in Indiana without a license. In the trial court, a conviction resulted. An intermediate appellate court discharged Williams, and the state appealed to the Supreme Court of Indiana.

The dental practice act of Indiana provides that, in charging any person with violating the act, "it shall be sufficient to charge that such person did, upon a certain day and in a certain county, engage in the practice of dentistry, he not having a valid license so to do, without averring any further or more particular facts concerning the same." The affidavit in the present case conformed to this requirement. Williams contended, and the intermediate appellate court upheld the contention, that the foregoing provision was unconstitutional because it violated a constitutional guaranty that, in all criminal prosecutions, the accused shall have the right to demand the nature and cause of the accusations against him. The Supreme Court held, however, that the affidavit was sufficient as against the constitutional objection raised. The substantive offense charged by the affidavit was the practice of dentistry without a license. All or any of the acts set forth in sections of the dental practice act defining the practice of dentistry may enter into the substantive offense, but whether one or all of them do so, there is but one substantive offense, namely, practicing dentistry without a license.

The dental practice act further provides that any person shall be considered as practicing dentistry (1) who owns or operates a dental office or (2) manages or conducts a dental office or (3) engages in practices included in the curricula of recognized dental colleges. These provisions, Williams contended, were not within the police power of the state and therefore unconstitutional. With this contention the Supreme Court disagreed. The clause "or engages in practices included in the curricula of recognized dental colleges," said the court, was as much within the police power of the state to enact as any of the other provisions of the section defining the practice of dentistry. This clause does not refer to the subjects taught in the dental college, the court pointed out, but to those things which are practiced as provided in the curriculums, evidently meaning the things practiced in the dental clinic, such as opera-

tive prosthetic dentistry, crown and bridge work, inlay and orthodontia. Any person therefore engaged in such practice would be practicing dentistry. Furthermore, the court continued, the profession of dentistry is not a business but one of the learned professions. It is not a business where one can procure a room and a manager to run it. Before a person may practice dentistry, he must pass a rigid examination and secure a license. If a person alone, or an association of persons who fail to have the necessary learning to pass the dental examination, can own, manage and operate a dental parlor with a licensed dentist in charge, then all the statutes regulating the practice of dentistry would be of no effect. The standards and ethics of the dental office, the class of workmanship and the fee would be regulated by the owner or manager. The purpose of the dental statute, continued the court, is to prevent any person from practicing dentistry who is not duly licensed and qualified, and any person who is not so qualified can neither directly nor indirectly practice dentistry. If one who is not qualified and licensed to practice is permitted to select and rent an office and then employ licensed dentists to do the actual work, either on a commission or on a salary basis, he would certainly be doing a dental business and would be doing indirectly what he could not do directly.

Accordingly, the Supreme Court reversed the judgment of the intermediate appellate court discharging Williams—*State v. Williams (Ind.)*, 5 N E (2d) 961.

Optometry Practice Acts Employment of Licensed Optometrists by Corporation—The defendant corporation operated in connection with a retail jewelry store a department equipped for the filling of prescriptions for eyeglasses. This department was in charge of a licensed optometrist employed on a salary by the corporation. He ground lenses, repaired glasses, filled such prescriptions as were presented, examined the eyes of customers and issued prescriptions for those customers whose vision he found defective. He made no charge for the examinations or prescriptions and no obligation rested on the customer to have the prescription so prepared by the optometrist filled in the defendant's store. The Georgia board of examiners in optometry, alleging that under the circumstances the defendant corporation was engaged in the practice of optometry, filed a petition seeking to enjoin that practice. The trial court refused to grant an injunction and the board appealed to the Supreme Court of Georgia.

A corporation said the Supreme Court of Georgia, as such, cannot itself qualify or be licensed to practice optometry. The question to be determined, therefore, is not whether a corporation as a fictitious legal entity can practice optometry but whether or not the employment by a corporation of a licensed optometrist constitutes such practice of optometry as is inhibited by the optometry practice act. That act, the court said, was passed to protect the public health against injury or harm which might result if ignorant, unskilful or incompetent persons were permitted to offer their services as optometrists. It was not enacted to protect the interests of persons engaged in the practice of optometry. The court disagreed with the contention of the board that optometry was a "learned profession" comparable to medicine. In the opinion of the court, the corporation's method of doing business was neither inimical to the health and safety of the public nor was it prohibited by the optometry practice act. The court, therefore, could see no reason why the injunction should issue.

For the reason stated, the judgment of the trial court refusing to issue the injunction was affirmed—*Georgia State Board of Examiners in Optometry v. Friedmans Jewelers Inc (Ga.)*, 189 S E 238.

Lobar Pneumonia a "Bacterial Trouble"—Death from lobar pneumonia said the appellate court of Illinois, second district, is a death from "bacterial trouble" within the meaning of a benefit certificate issued by the Fidelity Mutual Benefit Association, which provided that one fifth of the usual benefits would be paid to a member of the association who died of a "bacterial trouble" within one year of the issuance of the certificate—*White v. Fidelity Mut. Benefit Ass'n (Ill.)*, 6 N E (2d) 271.

Surgical Reconstruction of the Arthritic Cripple

DR PHILIP D WILSON New York This paper deals with the whole problem of surgical reconstruction of patients crippled by chronic arthritis. The fact is stressed that surgery becomes necessary only when the arthritic process is inactive. These remarks are confined entirely to the atrophic or rheumatoid type of arthritis. Various obstacles and problems must be dealt with before a decision can be made as to how much can be done. Multiple operations are often necessary and the patient's general condition and morale are important factors. It is important to distinguish between the arm problem and the leg problem, and the solution of either of these problems is a justifiable end in itself. Synovectomy is indicated chiefly in cases of chronic effusion. Flexion deformities of the joints particularly of the knee are best dealt with by the author's operation of posterior capsuloplasty when the amount of articular damage is slight. The object of this operation is to loosen and lengthen the posterior capsular ligament. When there is much bony change in the knee the deformity usually requires correction by supracondylar osteotomy. There are arguments against fusion or ankylosing operations on the knee or hip in this disease because in general the results are not good. In painful joints with much articular damage as well as in ankylosed joints, regardless of whether the ankylosis is fibrous or bony, arthroplasty is recommended. Some helpless cripples can be restored to a fair measure of independence.

a result of multiple operations performed at different periods. Surgical reconstruction offers hope to a large number of such individuals who are at present quite neglected.

DISCUSSION

DR ROBERT B. OSGOOD, Boston. I agree completely with Dr. Wilson. The first factor to be emphasized is the original plan to see the thing through which Dr. Wilson has proposed, not only surgically but psychologically. The patient's physical condition must, of course, be good, and he must be brought mentally not only to a state of acquiescence but to a state of enthusiasm with a burning desire for these procedures. The whole program must be visualized by him. He must beg for these measures, as these patients often will if the proposition is put to them properly. The cooperation of the patient is as important as is the skill of the surgeon. A half normal capacity to the person who has been completely disabled is worth much more than a return to full capacity to a person who has been only half disabled. These patients will comprise a grateful group. Dr. Wilson's method of handling these handicapped patients is deserving of the intelligent attention of all those interested in chronic arthritis.

DR M. H. DAWSON, New York. We are all deeply appreciative of what the orthopedic surgeon does for the arthritic cripple. Anything that helps to make this type of patient more mobile is a great blessing. There is one group of patients to which Dr. Wilson referred that bothers me. I noticed in his chart that he had several cases of synovectomy. I should like to know what he considers the proper indication for this procedure in a patient with chronic arthritis. If he could give a five year follow up on a number of cases it would be helpful. One sees in the arthritis clinic from time to time patients who have had synovectomy many years before and it is difficult to assess the value of that procedure. I should like to get a definite opinion from Dr. Wilson.

DR JOHN P. STUMP, New York. Any one who has had a chance to see Dr. Wilson's excellent postoperative results cannot help being impressed. One of the important observations made by Dr. Wilson, I fear, might be lost, and this observation should be given more attention. It is the fact that a great many deformities are the result of patients not having proper orthopedic attention in the early stages of the arthritis. It should be emphasized that early orthopedic management is essential in treating arthritic patients if deformities are to be controlled.

DR PHILIP D. WILSON, New York. I did not have any synovectomies in my group. The sixty cases referred to were posterior capsulotomies. The number of synovectomies was small. I am no more enthusiastic about the operation of synovectomy than is Dr. Dawson. I believe one must select cases for synovectomy with great care. The criteria are first a low grade or quiescent stage of arthritis, second, absence of joint limitation, third, persistence of swelling of the synovial capsule, thickening or swelling with tenderness as a rule with a fat pad on the front of the knee, on either side of the patella or chronic effusion. I think the chronic effusion is perhaps the greatest indication of all. When a joint has had a large amount of effusion for several years, unrelieved by a great number of aspirations or other procedures, I believe that synovectomy may be done. I agree with Dr. Dawson that synovectomy is an easy operation and there is great danger that it might be done promiscuously without proper selection. I do not believe at all in the claim that has been made by a good many surgeons that with synovectomy one gets rid of the focus of infection which is located there and which may be the cause of further propagation of the disease in other joints. I have never seen any results to back up that statement. One often sees after any operation a marked general improvement. I do not know why it occurs. It is seen after tonsillectomy. If these patients get better function in the knee are more active and their general activity is improved they improve by increased function. They appear to be better. I think that is the reason many surgeons make the claim that synovectomy gives a general benefit. I think it is purely a theory.

Critical Evaluation of Vaccine Therapy

DR EDWIN P. JORDAN, Chicago. This paper will appear in full in THE JOURNAL.

DISCUSSION

DR RALPH H. BOOTS, New York. It is unusual to listen to a paper on vaccine therapy without the announcement of a higher percentage of cures. I think Dr. Hench is responsible for the expression "come depression or prosperity, it is a poor season indeed which does not present its vaccine of the year." Certainly with regard to osteo-arthritis there seems no excuse to employ vaccine therapy. Regarding rheumatoid arthritis, our waning enthusiasm is best illustrated by the number of patients we have treated with vaccine therapy during the various years in our clinic. Ten years ago we employed vaccine therapy in 90 per cent of our patients with rheumatoid arthritis, five years ago about 40 per cent, and the past year approximately 15 per cent, so that we are relying less and less on vaccine therapy and more and more on general treatment of the patient. The enthusiasm for vaccine therapy about equals that for gold salt or sulfur therapy. Occasionally just as we are about to give up vaccine therapy entirely we encounter a remarkable result which may be due to a natural remission of the disease, to psychotherapy or to vaccine itself, so we continue with a small number of patients who do not improve otherwise. Dr. Jordan sums up the situation when he states that the use of vaccine in rheumatoid arthritis still rests on pure empiricism.

DR WILLIAM K. ISHMAEL, Oklahoma City. Dr. Jordan's timely discussion on the use of vaccines in the treatment of rheumatism again brings up the question of whether or not the action of vaccines is of value. This question leads me to present the following observations, which, I believe, offer definite proof that high titer fractional doses of thoroughly autolyzed bacterial antigens originated from cultures of arthritic patients given intravenously in doses as small as a 1:100,000,000 dilution of the water soluble equivalent of one autolyzed bacteria, will provide the typical leukocytic drop seen in other types of allergy. This injection when used as treatment is designated vaccine therapy, but it has occurred to me that the term vaccine should be reserved for the first group described by Dr. Jordan. Some characteristic term for the high dilution antigens used in the hypersensitive types of arthritic patients should be adopted. I suggest the term "autolyzed arthritic bacterins." The criteria that I have used to determine cases suitable for this type of therapy are (1) sedimentation test for bacterial activity or allergic phenomena, (2) leukocyte count with the Schilling hemogram, (3) agglutination reactions and (4) the leukopenic index for the autolyzed bacterins. The latter group has proved so strikingly characteristic that I wish to record in this discussion the record of eighty successive rheumatic cases. My method of leukopenic testing is the same as described by Vaughn and Rinkel in allergic reactions on food. Simple venous puncture, injections of physiologic solution of sodium chloride and injection of a 0.3 per cent solution of phenol in saline solution were used as controls. Furthermore, the leukocytic response to infinitesimal doses of the autolytic arthritic bacteria serves as a valuable guide to the differentiation between atrophic and hypertrophic types. These observations help substantiate Dr. Jordan's suggestion that immunologic and hypersensitive reactions to bacterial by products are separate and distinct, and the method is proposed as a new way of studying the latter. The autolytic arthritic bacterins used were made from a stock antigen selected from arthritic patients, attenuated by a 0.3 per cent phenol solution in saline solution. The dilution starts with 2,000,000 per cubic centimeter and after complete autolysis has taken place diluted as low as the equivalent of one one hundred millionth organism per cubic centimeter. It seems incredible that such a high dilution should cause a drop in the leukocyte count from 2,000 to 6,000 per cubic millimeter, which would mean a demobilization of from 20 to 50 per cent of the white cells in the capillary circulation of the skin. The dose used to provoke the leukopenic response produced a clinical response in about 88 per cent of the positive cases characterized by a feeling of euphoria and decreased pain and swelling. I

believe that these observations indicate the need for further study of the use of the highly diluted autolyzed bacterins in our armament of rheumatic therapy

DR WALTER BAUER, Boston Dr Boots, in a previous paper, stated that one of the advantages in treating patients with rheumatoid arthritis with vaccines is that it brings the patients back to the clinic regularly, thus giving one the opportunity to observe the course of the disease, allowing for better supervision of the patient and the prescribing of any other sensible therapeutic measures In addition, one gets to know his patient's problems better

DR EDWIN P JORDAN, Chicago The main point I had in mind was that vaccine therapy is still in the experimental stage

Proliferative and Degenerative Arthritis

DR ROBERT M STECHER, Cleveland Most cases of arthritis can be classified into two types, the proliferative type, which is inflammatory in nature, and the degenerative type, which shows no evidence of inflammatory reaction Ordinarily they seem to be two separate diseases without definite relationship This paper consists of the reports of six cases of degenerative arthritis which develop in the same joints which previously had been the seat of proliferative arthritis The identity and characteristics of proliferative and degenerative arthritis from the clinical, laboratory, roentgenologic and pathologic standpoints are discussed The roentgenologic changes in these cases are demonstrated with lantern slides Degenerative arthritis seems to result from a wearing out process of the cartilage which is fostered by old age or injury In the cases described the patients had an inflammatory arthritis, which completely subsided, but not until sufficient damage had been produced to cause the development of degenerative arthritis This conception may help to explain some of the marked deformities occurring in degenerative arthritis which cannot be explained adequately on the basis of cartilage deterioration alone

DISCUSSION

DR RUSSELL L HADEN, Cleveland Dr Stecher has reported observations on six patients who developed hypertrophy of bone around a joint following an acute septic arthritis The gonococcus was the proved inciting organism in three cases and the presumable cause in the others In three, ankylosis was the end result The question he brings up is whether these observations throw any light on classic rheumatoid arthritis and osteo-arthritis Hypertrophy of bone develops not infrequently in rheumatoid or other types of infectious arthritis It is especially apt to follow a septic arthritis Here however, the bone changes are secondary to the infectious process and not to the primary change in the cartilage characteristic of primary osteo-arthritis One should thus distinguish between primary and secondary hypertrophic arthritis When this distinction is made I see no evidence of a direct relation between rheumatoid arthritis and osteo-arthritis It is true that rheumatoid arthritis in a person with osteo-arthritis will speed up the degenerative changes Still these are entirely separate diseases and, with the exception cited, the rheumatoid arthritis influences the osteo-arthritis just as any other entirely distinct disease might I am also doubtful whether an infection can have anything to do with the causation of malum coxae senilis This is a typical primary degenerative arthritis I have never seen a patient with this condition who gave a history suggesting a preceding acute septic infection of the hip If infection were a factor, the history should certainly be suggestive in some cases at least

DR WALTER BAUER Boston I think all will agree that changes in the hip joint such as Dr Stecher described may be the end result of any septic arthritis I think he should have chosen a title which would have implied that he was going to speak concerning the end results in three cases of proved and three cases of probable gonorrheal arthritis The title The Importance of Proliferative Arthritis as One Cause of Degenerative Arthritis is misleading A previous proliferative arthritis does allow for the development of degenerative joint changes at an earlier age than would otherwise occur

However, Dr Stecher was dealing with degenerative and proliferative changes secondary to a previous gonorrheal arthritis and not proliferative arthritis Proliferative arthritis is a synonym for rheumatoid arthritis—a distinct disease entity, in no way related to gonorrheal arthritis The pathology of proliferative or rheumatoid arthritis is quite distinctive and should not be confused with gonorrheal arthritis Employing the term proliferative arthritis for cases of arthritis due to the gonococcus only adds confusion to an already confused subject One should always so far as is possible adhere to an etiologic classification of the arthritides After seeing the roentgenograms presented by Dr Stecher, one fact should be clear, namely, that extensive degenerative and hypertrophic changes may develop rapidly in any joint which has been the seat of a septic arthritis If the roentgenograms of such patients taken some years after the initial infection should be examined, there might be great difficulty in interpreting them correctly They might be called malum coxae senilis, whereas they are not In such instances a good history will often be the most helpful single factor in arriving at the correct interpretation I have been much interested in cases of so called malum coxae senilis Dr Smith-Petersen has done acetabuloplasties in thirty such cases Review of the clinical cases reveals various causes, such as previous septic arthritis, rheumatoid arthritis, slipped epiphysis or fracture Such a study emphasizes the necessity of our trying to be as specific as possible in the terminology we employ when speaking of the type of joint disease and its pathology

DR M HENRY DAWSON, New York I would like to suggest that the roentgenograms submitted by Dr Stecher are not roentgenograms of true cases of malum coxae senilis The roentgenologic picture of malum coxae senilis is characteristic and can scarcely be confused with any other condition There are four essential features narrowing of the joint space especially well marked in the weight bearing portion of the joint condensation of the subchondral bone, the occurrence of cystic areas of degeneration in the head of the femur and adjacent acetabulum, and finally, marginal lipping The appearance is quite characteristic and is entirely different from that seen as a result of an old infectious process

DR ROBERT M STECHER, Cleveland I cannot agree with either Dr Bauer or Dr Haden that all these cases are gonorrheal arthritis Three of them certainly are The remaining three in my opinion, certainly are not I do not believe that such a diagnosis is justified in the complete absence of history or symptoms of gonorrhea The term proliferative arthritis is a pathologic designation and indicates an inflammatory type of joint reaction Although rheumatoid arthritis is a proliferative arthritis, the latter term is more comprehensive than the former and includes acute proliferative or inflammatory arthritis Dr Bauer says there is no evidence in these cases showing what changes can take place in the joints in years to come Certainly there is not, but I have shown the changes which did take place in two years Unless one takes a good history, he says, one might think that the condition was malum coxae senilis I believe the patients will have malum coxae senilis I do not believe that malum coxae senilis is a specific disease It probably arises under a variety of circumstances Dr Bauer and Dr Smith-Petersen believe it may follow slipped epiphyses or result from damage done by acute proliferative arthritis I have presented evidence which I believe supports the last half of this contention I do not agree with Dr Dawson that malum coxae senilis presents an appearance quite different from that seen as a result of an old infectious process The hip cases here presented are of comparatively recent origin Despite this fact, they show more or less decrease of space in the weight bearing portion of the joint and also marginal lipping Dr Haden places great weight on the distinction between primary and secondary hypertrophic arthritis This distinction seems to me to be of importance only so far as it aids in determining the cause of hypertrophic arthritis This disease undoubtedly results from various stimuli regardless of which the end result may be the same I have attempted to show that it may follow quite promptly after a proliferative arthritis which has subsided

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1927 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Reduction of Intracranial Pressure with Hypertonic Sucrose Solution.—Jackson and his associates selected stuporous or comatose patients who showed signs of contusion of the brain (increased intracranial pressure and bloody fluid), usually with fissured fracture of the skull, for decreasing the intracranial pressure by the injection of a 50 per cent solution of sucrose. The patients were placed in the lateral position with the head on a level with the spine. In restless patients, local procaine anesthesia is used for the introduction of the spinal needle. The Queclenstedt test is applied to determine the patency of the cerebrospinal system. The solution is injected slowly into the median basilic vein of the forearm in amounts of 100, 200, 300 and 400 cc. Readings are then repeated, with the spinal needle attached to the mercury manometer at varying intervals up to forty-eight hours. In eight cases of cerebral injury with severe trauma the average reduction in pressure was 50 per cent; the least reduction was 16 and the greatest 66 per cent. The reduction is maintained for six hours and in some cases for as long as twenty-four hours. From 200 to 300 cc of solution is necessary in most instances to produce

these reductions because sucrose has only one-half the osmotic pressure effect as compared to dextrose. In three severe cases there was no reduction; one of these patients was dying. In two cases there was an increase in pressure. A slight increase in pressure from 34 to 36 mm of mercury was caused by 100 cc of the solution after four hours. In the other case, 400 cc caused an increase from 11 to 16 mm of mercury after two hours. In both these cases, a reduction was afterward obtained by the withdrawal of cerebrospinal fluid. Compared to dextrose, the reduction in spinal pressure with the sucrose solution has been greater, in some cases up to three times that produced by dextrose. There has been no secondary increase in cerebrospinal pressure except in two instances and no toxicity, and the patients have been relieved of headache and restlessness with a few exceptions. No increase in the sugar content of the cerebrospinal fluid has been noted. Hypertonic sucrose solution may be used as an adjunct in those cases of severe edema of the brain in which spinal drainage is not successful, and in cases of multiple fracture of the pelvis or extremities in which spinal drainage may be difficult or impossible. In cases in which spinal drainage is not productive of a marked fall in pressure, the edema of the brain may be pronounced and the use of hypertonic sucrose may be of greater benefit. Sucrose acts by withdrawing water from all the body tissues into the blood, which in turn throws off both fluid and sucrose through the kidneys by an active diuresis. Similar withdrawal of fluid may be obtained with hydragogue cathartics.

Foreskins Used for Skin Graft Purposes.—Ashley maintains that, of the methods used to cover large denuded areas, not one is simpler than the use of circumcised prepuces. In any hospital having an active maternity service, one may obtain all the foreskins necessary. If desired as grafts, but not required immediately, they may be kept in physiologic solution of sodium chloride in a refrigerator or may be embedded in ice cubes. Successful results have been obtained with prepuces that have been kept in the icebox in saline solution or ice cubes for as long as two weeks. They can be used not only where thin skin is required but also where thick skin has been destroyed, e.g. on the sole of the foot, as the general tendency of any graft is to take on the characteristics of the skin in its new location. These grafts might be used for chronic ulcers and to cover amputation stumps. The author does not dispute the superiority of autografts over isografts. Nevertheless his experience with the use of prepuces has convinced him that they are well worth using. He suggests that all foreskins available be saved. To avoid syphilitic infection it would be wise to investigate the donors carefully although it is not very likely that the spirochete will survive when the foreskins are preserved.

Caustic Burns of Eye.—In his experiments on rabbits with caustic burns of the eye Hubbard compares the effect of irrigation with water with the effect of irrigation with a weak neutralizing fluid. The caustics and irrigating solution were carefully measured and the time was regulated exactly by a stop watch. Between 80 and 100 per cent of the acid burns treated by irrigation with a weak alkali were definitely worse than the acid burn of the opposite eye treated by irrigation with

water alone. About 75 per cent of the alkali burns treated by irrigation with a weak acid were definitely better than the alkali burn of the opposite eye treated by irrigation with water alone. The observations substantiate the theory that a soluble alkaline proteinate does not protect against further injury, although an insoluble acid proteinate does. If sulfuric acid is a typical acid, an eye with an acid burn should be irrigated with water and not with a weak alkali. If sodium hydroxide is a typical alkali, an eye with an alkali burn should, when possible, be irrigated with a weak acid.

Ageusia After Mastoidectomy.—Ho studied the disturbances of taste of otitic origin that occurred in patients from the otolaryngologic service of the Memorial Hospital, including four from the City Hospital of Worcester, Mass., from December 1936 to May 1937. Especial reference was made to patients who had had operations on the ear particularly radical mastoidectomy. In a group of twenty-one cases of acute disease of the middle ear there was no change in the sensation of taste, the reason being that the chorda tympani nerve was not affected either by the acute disease or by the surgical procedure. Of eighteen patients in whom chronic suppuration of the middle ear developed, changes in the sensation of taste were noticed in some and not in others. This difference depends on two factors—the resistance of the chorda tympani nerve to the infection and/or the effect of the pathologic changes of chronic otorrhea on the chorda tympani nerve. Many patients with aural cerumen have been questioned but not one person was observed with a positive change in the sense of taste. In the only case of ossiculectomy in which a follow-up study was possible, the patient showed a change in the sensation of taste on the anterior portion of the tongue corresponding to the side operated on indicating that the chorda tympani nerve had been injured owing to its close anatomic relationship to the malleus and the incus. In a group of seventeen patients who had undergone radical mastoidectomy in which the chorda tympani nerve was destroyed, the sense of taste on the anterior two thirds of the tongue on the side operated on was invariably absent. Loss of taste was present in the three cases of paralysis of the facial nerve following mastoidectomy. A change in the sensation of taste was present on the anterior portion of the tongue on the side operated on in two cases after modified radical mastoidectomy. This disturbance of taste, instead of complete ageusia, must be attributed to some change in the chorda tympani nerve. In cases of disturbance of taste of otitic origin the patient has no consciousness of any such change. Yet clinical tests of taste bring out the difference.

Urea in Diseases of Ear, Nose and Throat.—Lewy found a 2 per cent solution of urea beneficial in reducing metastases in certain types of infected necrotic carcinoma. Its value for infected wounds of the ear and throat and infected wounds of the neck and the floor of the mouth parallels the excellent results in the treatment of infected wounds in other parts of the body. Its specific effects seem to be elimination of odor, proteolysis of necrotic tissue and stimulation of granulation and epithelization. In order to observe its value as a therapeutic agent a more comprehensive study of this substance seems to

be indicated. From two to four cases of each manifestation are reported in which treatment was beneficial: carcinoma, Ludwig's angina, maxillary sinusitis, cervical adenitis, otitis media and mastoid wounds.

Cutaneous Reaction to Pneumococcus Vaccines.—Weil and Phillips found that it is possible under certain conditions to evoke a reaction in the skin of rabbits by injecting killed pneumococci and that it is also possible to neutralize specifically such a reaction with antipneumococcus serum. Rabbits from 4 to 6 months old were used. A heretofore unknown property of the pneumococci is shown. The substance which evokes the cutaneous infiltration of rabbits is distinguished by qualities which make it necessary to assume that it is not identical with the type-specific polysaccharide. In contrast to the S substance, it is easily destroyed by moderate heat (from 56 to 60 C.) and it disappears, or is at least damaged, by the changes taking place as the culture becomes older. This substance ('irritating substance,') must be linked in some way with the specific soluble substance of Heidelberger and Avery, because it is neutralized quantitatively by the same antibody which is directed against the S substance. The existence of Boivin's hypothetical substance, which is not proved, would be a perfect connecting link between the knowledge of the S substance and the authors' observations, if what they call 'irritating substance' would be the antigenic complex postulated by Boivin. The S substance of the pneumococcus is not toxic and not antigenic as is the case with the polysaccharide of the Salmonella group when separated from the 'antigenic complex' by acid hydrolysis. Both the polysaccharide and the S substance of the pneumococcus determine the specificity of the whole complex and are precipitated *in vitro* specifically. The neutralization test is comparable to the neutralization in the skin of true toxins by antitoxic serum. The neutralizing effect of antipneumococcus antibody is of primary

tical use, because it presents a new method for the evaluation of serums. The infiltration reaction is prevented specifically when antipneumococcus serum is injected simultaneously with the vaccine. The neutralization is strictly type specific and allows a quantitative estimation of the antibody content within a range of ± 20 per cent.

Exophthalmic Goiter and Psychosis—Among more than 5 000 cases of exophthalmic goiter Bram obtained a history of psychosis in forty-two, chiefly of the manic-depressive type. Of the total number, twelve cases occurred in surgically untreated cases, the remainder in patients thyroidectomized months or years before. Of the thirty postoperative cases, the history pointed to the existence of the psychosis preoperatively in ten cases, while in the remaining twenty the psychosis appeared for the first time after discharge from the hospital. In all the postoperative cases, despite such residuums of exophthalmic goiter as moderate exophthalmos, tremor, moderate tachycardia with an irritable heart, insomnia and fatigability, the basal metabolism rate was not excessive, varying from plus 20 to minus 8 per cent. In not a single instance could the presence of a significant family history of psychosis be determined. Despite the coexistence of the two diseases, no definite causal relationship has been established between the two conditions. A psychosis may be superimposed on a preexistent exophthalmic disease, or exophthalmic disease may be superimposed on a preexistent psychosis. In either event the complication aggravates the prior malady and renders the clinical picture and the prognosis graver. In the event of a complicating psychosis in exophthalmic disease the psychosis becomes the major therapeutic problem, treatment of the exophthalmic goiter alone is usually futile.

Pathology of Lungs and Other Organs in Silicosis—Matz determined the gross and microscopic changes of the lungs and extrapulmonary organs and tissues in twenty-three silicotic patients who came to necropsy in the hospitals of the Veterans Administration. It was thought that a study of the morbid changes in the silicotic patient might give information which would explain certain of the clinical symptoms and signs of the disease and its complications as well as the causes of death. 1 Involvement of the pleura may be the cause of the chest pain which is invariably present. 2 Fourteen cases presented evidence of an associated tuberculosis. In eight instances the two conditions were discernible as separate and distinct diseases and in six it was not possible to ascertain a separate background for either disease. The combined condition was

classified as silicotuberculosis. 3 Tuberculosis complicated the incipient as well as the advanced stages of silicosis. Extrapulmonary tuberculosis was a frequent accompaniment. 4 In five instances all lobes were affected, in two the disease was present in the right and left upper lobes, both lower lobes were affected in one case, the left lower lobe was affected in one case, in five the distribution of the tuberculous disease was in one or both upper lobes as well as in the right middle or in one of the lower lobes. 5 Only eight of the twenty-three cases gave evidence of emphysema. 6 Chronic lymphadenitis was found in eleven of the twenty-three cases, the tracheobronchial lymph nodes were affected in nine cases. 7 Disease of the liver was present in fourteen cases, three showed evidence of hypertrophic cirrhosis. 8 In twelve instances disease of the spleen was present—six showed the presence of chronic splentitis. 9 The cardiovascular system was a frequent site of disease. Hypertrophy of dilatation of the heart, or a combination of the two conditions was observed in eighteen necropsies. 10 Cardiac hypertrophy and/or cardiac dilatation was found in the early as well as in the advanced stages of silicosis. 11 Cardiac hypertrophy and/or dilatation was found in silicosis complicated by tuberculosis. 12 Arteriosclerosis of the aorta was present in nine of the twenty-three cases, in five of the nine cases there was concomitant cardiac hypertrophy or dilatation. The average age of the group was 52.8 years. 13 Chronic passive congestion of the various organs, which was due to cardiac failure, was observed in fourteen cases.

*Migraine Syndrome: Comments on Its Diagnosis, Etiology and Treatment T J C von Storch Boston—p 247
Some Thoughts on Osteopathy S Rushmore Boston—p 267

Migraine Syndrome—Von Storch suggests that, in reporting cases of migraine, utilization be made of the four cardinal components of the syndrome: recurrent headache, preferably but not necessarily hemicranial in type, associated visual symptoms, classically scintillating scotomas, temporary gastrointestinal phenomena, usually nausea or vomiting, and hereditary migraine diathesis, occasionally an epileptic history. No single pathologic process nor its presumed mechanism will explain conditions observed in an entire group. On the other hand, any one of the allergic, colonic, endocrine, duodenal, hereditary or psychic processes may be the primary factor in certain cases. In other words, each etiologic factor appears to be reasonable for a selected group, but none for an entire series. It would seem, therefore, that the underlying pathogenesis of the migraine syndrome is multiple. A mechanism which may be common to all types of migraine is dilatation of the dural and possibly temporal arteries with consequent stimulation of their periarterial plexuses. This seems to be the only mechanism related to the common symptom headache. Ergotamine tartrate is the most efficient non-sedative means of aborting or terminating individual attacks of migraine. Prevention of the attacks depends on determination of the underlying pathologic condition present in each individual case.

*Sequence of Infectious Diseases in Upper and Lower Respiratory Tract: Anatomic and Clinical Considerations A Settel New York—p 1435

Infectious Diseases in Respiratory Tract—Settel gives the following reasons for believing that within the limits of the respiratory system morbid conditions tend to pass from the upper to the lower part of the respiratory tract rather than in the reverse direction: (1) aspiration of secretions with their bacterial products, by gravity and suction, (2) muscular action in the pharynx as in swallowing and hawking, (3) ciliary action in the upper and lower part of the respiratory tract except

in the middle and lower parts of the pharynx, where the epithelium is of the stratified squamous variety due to digestive function, (4) neurogenic tonus of the sympathetic and parasympathetic systems, both of which supply the organs of respiration, and (5) vascular and lymphatic pathways for the spread of infection. The evidence that certain disorders of the lower part of the respiratory tract, notably chronic non-tuberculous bronchitis, bronchiectasis and bronchial asthma, have followed this sequence from the upper part of the respiratory tract is based on a number of observed facts that make it seem conclusive. 1 The same pathogenic organisms are found in the primary foci as in the metastatic lesion of the lower part of the respiratory tract. 2 Disorders of the lower part of the respiratory tract have repeatedly improved and in many cases been entirely cured after the infection in a sinus has been cleared up by suitable treatment. The rapidity with which this change takes place after eradication of a sinus infection argues strongly in favor of such a sequence. 3 It may be possible to prove that an infection has come down from the upper part of the respiratory tract to the lower, by inoculating into animals the pathogenic organisms obtained from smears of the nose and sinuses, on the one hand and from the sputum, on the other, and then comparing the results. 4 The frequency with which an infectious disease is found to exist simultaneously in the lower and upper parts of the respiratory tract cannot be regarded as an accident but is evidence that an infection at work in one locale has sent its emissaries, as it were, to found a colony in another region.

Ultraviolet Irradiation and Autohemotherapy in Syphilis—Baer carried out the following procedure in the treatment of thirty patients who presented persistently positive serologic studies. The entire body was exposed to the ultraviolet rays with graduated erythema dosage twice a week. Following the first ten treatments (thirty treatments in all) and the last ten treatments 15 cc. of autogenous blood was administered into alternating gluteal areas half an hour after irradiation. Wassermann Kahn and Hinton tests were performed prior to and at the conclusion of the course of treatment. The colloidal gold globulin and Wassermann tests were performed on the spinal

fluid in most of the cases. Polymorphonuclear leukocyte and differential counts were made prior to and after each irradiation. The material represented the usual types of Wassermann fast patients who have received but have not serologically responded to routine treatment with arsphenamine, tryparsamide, iodobismutol, preparations of bismuth, mercury compounds, potassium iodide and sodium iodide. Of the thirty patients placed under this regimen, twenty-seven were observed throughout the study. Ten patients showed a complete reversal of their serologic studies. Five patients who had studies of the spinal fluid prior to the institution of the treatment, showed a simultaneous complete reversal with the blood. Clinically, five were asymptomatic, two tabetic and three belonged to the dementia paralytica group. All this group gained in weight and stated that they felt better, slept better and had more desire to do things. A study of the blood counts before and after each treatment did not reveal any significant data and gave no clue as to the role the leukocytes may have played in the immunologic phase. There was no definite trend of a curve following each treatment or during the course of the treatment. Of the seventeen patients who did not respond to this treatment, clinically eleven were asymptomatic, one showed an interstitial keratitis and congenital syphilis, two showed dementia paralytica and tabes with cardiovascular changes, and three had dementia paralytica. There were no changes noted in the blood, the blood count or the spinal fluid. The foregoing treatment should not supplant chemotherapy or fever therapy but can be used in the hopeless cases when these forms are contraindicated and have been unsuccessful.

Experimental Meningitis in Guinea-Pigs—A continuation of the effects of injections of meningococci and meningococcus products into the cisterna magna in guinea pigs is given by Branham and her collaborators. Their earlier experiments were reported in 1932. Young guinea pigs weighing from 200 to 250 Gm were inoculated intracisternally, under ether anesthesia, with living cultures of meningococci, with heat killed cultures with filtered suspensions of living cultures and with broth filtrates. Weight and temperature were recorded daily for each animal as long as it was under observation. The cultures were of freshly isolated strains. The dose given to guinea-pigs usually varied between 10,000,000 and 100,000,000 meningococci, depending on the virulence of the strain. The number of meningococci injected was contained in a volume of from 0.2 to 0.3 cc of Ringer's solution. A purulent meningitis was produced alike by living meningococci, by killed cultures, by Berkefeld filtrates of suspensions from agar cultures (suspension filtrates) and by filtrates of broth cultures. The meningeal exudate appeared in from three to five hours. It was predominantly purulent in character, was denser on the base of the brain and between the brain stem and the occipital cortex and was often accompanied by congestion and hemorrhage. Fibrin was most often evident after inoculation with killed cocci. The sheaths of perforating and less often deep vessels were often infiltrated by purulent exudate. Purulent thrombosis was not infrequent, being especially common after inoculation with killed cocci. Purulent exudate in the ventricles occurred in the majority of the animals inoculated with living or killed cultures and in about 75 per cent of those receiving broth filtrates and dying in less than thirty hours but was infrequent with the suspension filtrates. Choroid plexus infiltration was correspondingly frequent. Purulent infiltration of the brain substance abutting on the meninges or ventricles was found in more than 50 per cent of the animals inoculated with cultures or broth filtrates. Other less frequent features of the process were perivascular hemorrhages, hilar marginal or central abscesses and suppurating ependymal ulcers in the ventricles. Pericellular edema in the cerebral cortex and turgescence and vacuolation in the nuclei of the brain stem were observed fre-

quently, especially in animals surviving more than twelve hours. In subsiding reactions the meningeal exudate decreased in amount and became partly or entirely lymphocytic in character, the involvement of intracerebral vessel sheaths disappeared and the ventricular exudates decreased and disappeared. Plexal infiltration became lymphocytic or disappeared entirely. With filtrates and killed cultures evidence of subsidence was observed on the second day, while with living cultures no decrease in the reaction was apparent until after three days. It appears that meningococcal meningitis in guinea-pigs may be either an infection or an intoxication. In both infection and intoxication the clinical and histopathologic pictures were the same.

Lack of Protection in Antimeningococcus Serum—In studying the effect of antimeningococcus serums on meningitis in both rabbits and guinea-pigs Branham and Pabst found that, although meningitis was easily produced in these animals, they were not protected to any appreciable degree by the serums when these were administered intracisternally, intraperitoneally or intravenously. Some of the experiments have suggested that with more perfect methods of concentrating the serums better protection may be obtained.

Coutard's Method of Treatment of Cancer—Since the results of Coutard therapy in the treatment of cancer of the larynx, pharynx and hypopharynx have been so far superior to any present or previous method, Chamberlain and Young believe that no other procedure should be considered when roentgen treatment for the disease at these sites is indicated. The same statement holds for cancer in certain other organs, for example, the cervix, breast, bladder, esophagus, bronchus and rectum, although it is often necessary to modify the dosage depending on the size and location of the tumor and the condition of the patient. In those lesions which respond to Coutard therapy better than to "massive doses," the advantage of the protracted fractional dose method must rest on the existence of a more rapid "recovery rate" in the skin than in the tumor. There are tumors requiring massive doses just as surely as there are tumors that require the method of Coutard. Certain small superficial growths are completely destroyed by a single large dose of from 3000 to 5000 roentgens with complete assurance that the resulting ulcer, of small size, will heal completely. For example, a small or moderate sized isolated nodule of recurrent mammary cancer in an accessible or superficial location. A plan of monthly doses of from 300 to 800 roentgens (usually in a three or four day series) is considered by the authors whenever they are faced with (1) a highly roentgen resistant tumor and a microscopic structure that indicates a high degree of tissue differentiation (fibrosarcoma, neurofibroma metastasizing thyroid adenoma) or (2) when the element of vascularity is an important factor (hemangioma, certain telangiectatic tumors of the spinal canal, some highly vascular but relatively radiation-resistant sarcomas of the bone). While the literature appears not to contain any analytic references to this type of technique it is obvious that Newcomet, Ewing, Ginsburg and others have consciously or subconsciously adopted some such method.

Tuberculosis of the Breast—Hudgins says that 1 Tubercle bacilli may enter the breast through the skin or the nipple by an abrasion or other breaks in the continuity of the integument. 2 They may enter the blood stream and circulate without actually having formed an original demonstrable focus in the body. Such organisms in the blood stream may be the causative agent of a mammary tuberculosis with perhaps no other foci. 3 Infection through the lymph system usually occurs from the axillary glands, though the spread may occur from other glands, chiefly the tracheobronchial, cervical, supraclavicular or retrosternal. 4 Infection by direct extension may occur, such as infection from the skin over the breast. Trauma could be definitely traced as a possible etiologic factor in only 8 per cent of the 361 cases reported in the literature up to January 1935, and a preceding attack of mastitis in only 6 per cent of the cases. Ten instances were specified in which the onset occurred during pregnancy and fourteen cases in which the mass was noted during lactation. The chief symptom causing the patient to present herself for examination is a "mass in the breast." Next in order were "mass with discharge," "swelling of entire breast" and "mass with pain and discharge" all being common. Exclusive of "mass," "retracted nipple" was complained of most frequently, and "axillary gland," "discharge from the nipples" and "ulcer" each ranged from 1 to 2 per cent. Pain is an early and constant symptom. Cancer of the breast does not give pain or tenderness early. If, then, pain or tenderness is found, it practically rules out cancer and obviates the necessity of considering an extensive mutilating operation and may be used as an important point in the differential diagnosis. The skin is found to be involved frequently. It is more frequently attached to the mass than discolored. The term "orange skin" is used to describe the appearance of the surface overlying the mass at times. Discoloration is usually a reddening. The nipples were found to be retracted in 27 per cent of the cases and a discharge could be expressed in 6 per cent. The retracted nipple gives an added hazard in the problem of differential diagnosis between cancer and tuberculosis. Axillary nodes were found in 41 per cent of the cases, making this of definite diagnostic value in some differential points (fibroma, cysts, and the like). There seems to be a preference for the tuberculous mass in the upper outer quadrant. Tuberculosis of the breast is a rapid growth. Sudden changes in size and contour of the breast with early involvement of the axillary nodes cause the patient to come to the physician. In spite of this urgent local symptom, the general condition of the patient is remarkably good. Nodular tuberculous mastitis is by far the most common form of acid fast involvement of the breast, and this general group is divided into two classes: nodular discrete and nodular disseminated or confluent. The tuberculous mass is irregular in contour, fairly well defined and usually tender. It is of irregular consistency. The benign growths that must be excluded before a diagnosis of tuberculosis of the breast can be made are fibroma, cysts, carcinoma (including Paget's disease), sarcoma, pyogenic infections, syphilis and actinomycosis. Simple mastectomy is the operative surgical procedure of choice.

Treatment of Keratomalacia—Aykroyd and Wright determined the vitamin A activity of red-palm oil by experimentally producing in rabbits a condition resembling clinical keratomalacia. They cured these characteristic lesions of the eye by giving the rabbits from 0.5 to 2 Gm of red palm oil. Then they carried out a clinical trial using 10 minims (0.6 cc) of the original oil in an emulsion as an average dose for children between 5 and 10 years of age a suitable allowance being made for younger and older patients. This was given twice daily. Difficulties are encountered, one of which is the possibility that a beneficial effect on cases of deficiency may result from simply admitting the patients and placing them on a hospital diet. In three instances, however, the authors were enabled to treat and follow up patients suitable for observation who remained living under the identical domestic conditions in which they developed the syndrome. The only change in their daily routine was the addition of red-palm oil emulsion to their diet. In these the improvement was so definite that they concluded that, so far as the strictly limited observation goes, the red-palm oil alone acted in a curative capacity, supplying the necessary factor or factors in the same way as cod liver oil had done previously. Most of the patients with keratomalacia treated in the hospital were infants and young children. Cessation of deterioration may be observed within a week and a definite improvement within a fortnight from the commencement of treatment with the red-palm oil. The average vitamin A content of seven samples of cod liver oil tested was about 300 micrograms of vitamin A per gram while the carotene content of three samples of red-palm oil averaged about 500 micrograms per gram. Most of the samples of cod liver oil were obtained by local purchase. One microgram of carotene and 1 microgram of vitamin A, as estimated by Des method, are roughly equivalent to 1 and 26 international units, respectively.

Placental Infection in Induced Labor—Penfold and Butler record the results of the bacteriologic examination of 114 placentas, in forty-six of which labor had been induced with the rectal tube, in the remainder surgical induction of labor was carried out. In addition, in those cases in which the child failed to survive, cultures were also obtained from the fetus in most instances. Placental infection was detected two and a half times more often following the surgical induction of labor than in those cases in which no such operation had been performed. Of the forty-six placentas from cases in which induction had been practiced, twenty-eight were infected, thirteen with *Bacillus coli* and four with *Bacillus welchii*, indicating the fecal origin of the infections. Two of the thirteen placentas infected with *Bacillus coli* were also infected with *Bacillus welchii*. Among the sixty-eight controls only sixteen yielded growth, and in no instance were the organisms of a characteristic fecal type. Among the control group infection of the placental vessels was never detected but among the forty-six induced cases organisms were cultivated from the blood of these vessels in fourteen instances. Of the sixteen strains of bacteria isolated from the placentas from normal labors, only three were able to grow in the presence of air. The authors do not consider that the ten strains of *Staphylococcus albus* and the six strains of aerobic diphtheroids isolated from the placentas of the patients whose labors were induced were contaminants introduced during the making of the cultures, since such bacteria were not obtained from any of the control group. They believe that these bacteria were enabled to grow up into the uterus following the operation of induction. They were possibly fecal in origin or more likely came originally from the skin and invaded the placenta together with the fecal organisms introduced, since in all but two instances they were present in the placenta in association with typical varieties of fecal bacteria. A prolonged interval between the induction of labor and the delivery of the child increases the risk of infection of the placenta. Placental infection is not dependent to any great extent on the maternal condition or on the age of the fetus. The infections of the placenta with *Bacillus coli*, aerobic nonhemolytic streptococci and *Bacillus welchii* have been associated with a high infantile mortality. Mixed infections of the placental tissue and infections of the large fetal vessels of the placenta are especially serious for the infant. The bacteria cultivated from the dead infants are usually similar to those obtained from the placenta. When additional organisms are present in the fetus, their source is probably from infected amniotic fluid. There is a high correlation between fever in the mother and infection of the placental tissue.

- *Polypeptides of Blood and Cerebrospinal Fluid in Dementia Paralytica
H. Claude, J. Dublneau, P. Masquin and Mlle. Bonnard —p. 1
Dynamic Concepts and Epileptic Crisis S. E. Jelliffe —p. 15
Reflex Epilepsy A. Radovici, M. Schachter and S. Kisilev —p. 26

The Polypeptides in Dementia Paralytica—Claude and his associates studied the variations of the polypeptides before, during and after malaria or fever therapy in patients with dementia paralytica. They found that the polypeptide content of the cerebrospinal fluid is often increased in patients with dementia paralytica. This increase may be independent of the polypeptide content of the blood and may exist without a sign of hepatic insufficiency. In these cases one is led to admit a formation in situ of the polypeptides of the spinal fluid. Leukocytolysis has recently been suggested as favoring this increase in the polypeptides of the spinal fluid. But the authors do not consider this the only causal factor. The polypeptide value differs in the course of dementia paralytica. After malaria treatment it decreases, but it varies in different cases; it is relatively high in patients in whom the clinical results are negative, but it is practically normal in those in whom the process shows a favorable development. In some of the latter cases the decrease in the polypeptides of the spinal fluid has been known to be in evidence in the course of the malaria therapy and during the following months. Thus it seems that the curve of the polypeptide content of the spinal fluid has prognostic significance. The return to normal values permits hope of a favorable development.

Journal de Medecine de Lyon

- *Masked Forms of Cancer of Transverse Colon A. Cade and M. Milhaud —p. 447
*True Pyloric Ulcer C. Garin and P. Bernay —p. 453
Treatment of Tetanus of Human Subjects by Tetrachlorethylene C. Garin —p. 457
*Pseudo-Esophageal Form of Bronchial Cancer Rebattu, Gravier and Sprecher —p. 459
Mega Esophagus and Stenosis of Terminal Portion of Esophagus C. Bocca —p. 463

Masked Forms of Cancer of Transverse Colon—Cade and Milhaud show that the diagnosis of cancer of the transverse colon is often difficult. In the beginning as well as during the further evolution these cancers may present an atypical symptomatology. Among these masked forms those with a pseudohepatic symptomatology are especially difficult to identify. The authors report a case in which the diagnosis remained uncertain to the end, because of the complex clinical aspect and because the patient previously had had malaria and dysentery. During the time the patient was under the observation of the authors the patient had fever. It is well known that cancers of the large intestine may be accompanied by fever, but this symptom is also a frequent source of error. At different times the patient also presented symptoms of colitis and of dysentery. The authors admit that the simulation of dysentery by cancer is not rare but that it usually occurs in rectosigmoidal cancer, rarely in cancer of the transverse colon but they also discuss the possibility of a concurrence of dysentery and cancer. They emphasize that methodical and repeated x-ray examinations are of great value in cases of this type.

True Pyloric Ulcer—According to Garin and Bernay, true pyloric ulcer, that is, ulcer of the pyloric sphincter, is relatively rare. Its clinical aspects vary. The pain, which is usually severe, is generally the principal sign. The development of a stenosis is not particularly frequent. The chemistry is often without significant aspects. Gastrophotography may show lesions of a gastric character. Roentgenoscopy when done with great care is of much help in the identification of pyloric ulcer, but in a considerable number of cases the diagnosis proves extremely difficult.

Pseudo-Esophageal Form of Bronchial Cancer—Rebattu and his associates describe the clinical history of a man aged 53 who asked medical advice on account of vocal disturbances which had begun suddenly, during complete health several weeks before. Examination revealed paralysis of the left recurrent nerve with immobilization of the vocal cord on the median line. The other vocal cord was practically normal as were

the other portions of the larynx. Auscultation, palpation of the neck and examination of the nervous system revealed nothing abnormal and it appeared as if the recurrent paralysis originated from a mediastinal lesion. Later the patient developed progressive dysphagia. Repeated esophagoscopies finally suggested a submucous neoplasm of the esophagus. There were no signs of syphilis or tuberculosis. On several occasions the patient had blood in the sputum and bronchoscopy was resorted to. This and biopsy finally disclosed the bronchial tumor, but until the end the symptoms were those of an esophageal stenosis. The authors point out that tracheobronchial cancer is not the only lesion which manifests itself by dysphagia and simulates esophageal cancer. All disorders in the region of the mediastinum are likely to compress the esophagus. The authors think that in all mediastinal syndromes, in which the clinical diagnosis is often extremely difficult, endoscopy (esophageal and bronchial) is of primary importance and is superior to roentgenologic examination, which does not always give conclusive results.

Presse Medicale, Paris

45 1219 1234 (Aug. 25) 1937

- *Serologic Diagnosis of Infectious Mononucleosis A. Durupt —p. 1219
Clinical Significance of Electric Potential of Cells R. Keller —p. 1221

Serologic Diagnosis of Infectious Mononucleosis—After citing fever and cervical or general adenopathy as the most common symptoms of infectious mononucleosis, Durupt points out that these two essential symptoms are accompanied by angular symptoms, slightly enlarged spleen and a leukocytic formula that is characterized by a more or less pronounced mononucleosis. He also shows that various terms have been applied to this disorder, such as Pfeiffer's glandular fever and monocytic angina. Until now, the diagnosis has generally been based on the hematologic examination, which reveals a leukemoid formula. But this leukemoid blood picture makes it difficult to decide whether the disorder is benign, that is, an infectious mononucleosis, or a lymphoid leukemia with a fatal prognosis. The author shows that for this reason a serologic diagnosis of infectious mononucleosis, which was developed by the investigations of Paul and Brunnel and those of Davidsohn, is of great value. This serologic reaction is based on the presence of an abnormally large quantity of heterophilic antibodies (against sheep corpuscles) in the blood of patients with infectious mononucleosis. It is made in two stages. The first part of the test determines the agglutinating power of the patient's serum for the erythrocytes of sheep and the second part investigates whether the antishape agglutinins are susceptible to absorption by the antigens of Forssmann. The author describes the technic of these procedures (see also *THE JOURNAL*, Jan. 23, 1937, p. 289) and reaches the conclusion that the serologic diagnosis of infectious mononucleosis deserves a place in current laboratory practice. Its technic in two stages is as simple as that of the Wassermann test.

- *Variations of Blood Corpuscles in Experimental Catatonia from Typhoid Bacillus Toxins A. Milella and F. Barbanente —p. 675
Resistance of Group Specific Properties of Urine to Physical and Chemical Agents F. Tarantino —p. 704

Variations of Blood Corpuscles in Experimental Catatonia—Milella and Barbanente say that it is possible to induce experimental catatonia in dogs by means of intravenous injections of filtrates of the toxins of typhoid bacilli. The filtrates are prepared by filtering cultures of typhoid bacilli through a Chamberland filter of the B type. The symptoms (immobility, spontaneous and induced negativism, complete and segmental catalepsy and catatonia) are similar to those of catatonia in men. At the same time that the symptoms of experimental catatonia appear the crisis of the blood of the animals undergoes the same changes as those caused by typhoid in the blood of men. The changes are diminution of the erythrocytes, leukopenia which is followed by leukocytosis, neutropenia and lymphocytosis. There is a shut to the left in Schilling's hemogram. Diminution of the liver glycogen which is induced in the animals by fasting, increases the catatonic symptoms, intensifies the variations of the crisis of the blood and causes appear-

ance of polynucleated neutrophils with toxic granulations in the protoplasm. The identity of experimental catatonia, induced by the toxin of the typhoid bacilli, with catatonia in men and the simultaneous appearance of changes of the crisis of the blood, also induced by the typhoid toxin, which are similar to those taking place in the blood of patients suffering from typhoid, show that the typhoid toxin is the only cause of the two different phenomena. Catatonia originates in the harmful action of the toxin on the central nervous system, especially the cortex and centers in the midbrain, whereas the changes of the crisis of the blood originate in organic reactions to the toxin.

23 729 780 (July 30) 1937

- *Action of Decoction of Seeds of *Lupinus Albus* on Glycemia Induced by Administration of Dextrose in Normal Persons and in Diabetic Patients A Ferrannini and M Pirolli—p 731
Biochemical and Histologic Changes of Muscles from Mechanical Immobilization Changes of Water Content and Dry Residues N Toro—p 749
Progressive Chronic Articular Rheumatism Clinical Forms and Social Importance L Di Prisco—p 758

Action of Seeds of *Lupinus Albus* on Glycemia—Ferrannini and Pirolli used the following method. Five hundred grams of *Lupinus albus* seeds was made into flour and boiled in 600 cc of water. As the volume of the decoction was reduced by boiling to 350 or 400 cc, water was added in order to bring it to 500 cc so that 50 cc of the decoction would correspond to 50 Gm of the seeds. By experimenting on rabbits it was found that the decoction does not modify glycemia and is nontoxic. The action of the decoction was then studied on two groups of persons: those with a normal metabolism of carbohydrates and diabetic patients with glycosuria and without complications. Both groups were kept at rest before and during the tests, which were made on stomachs fasting for eighteen hours. The curves of glycemia were determined before and one-half, one, two, three and four hours after administration of 0.75 Gm of dextrose per kilogram of body weight. The dextrose was dissolved in 200 cc of water the first day of the test. Two days later the second test was made. The dextrose then was dissolved in 50 cc of the decoction of *Lupinus albus* and brought to a volume of 200 cc by adding water. It was found that the decoction of *Lupinus albus* increases the tolerance of the body to carbohydrates, slightly in normal persons and intensely in all diabetic patients. The seeds of *Lupinus albus* induce hypoglycemia without causing any disturbance in the patient. The authors point out the possible application of *Lupinus albus* in substitution for insulin or during suspension periods of insulin administration.

*Modifications of Myelogram and of Peripheral Blood in Pulmonary Abscess A Bertola and M Ravetta—p 635

Modifications of Peripheral Blood in Pulmonary Abscess—Bertola and Ravetta studied the modifications of the peripheral leukocytic formula and of the myelogram in eight cases of pulmonary abscess. In five cases the abscess was of metapneumonic origin, in two cases it developed in patients suffering from chronic bronchitis and in one it was an amebic abscess of the lung. The blood for counting cells was taken from fasting patients. The puncture for obtention of the sternal medulla was done at the second and third intercostal space with a needle long enough to obtain fragments of medullary tissue. The myelograms were made by examination of several slides, with no less than 1,000 or 1,500 cells on each slide. The authors found that in cases which follow a grave evolution there are a relative increase of the granuloblasts in the blood and in the medullary tissue and absence of eosinophils in the blood and of myeloid and histoid cells with eosinophil granulations and of plasma cells in the bone marrow. In cases which follow a favorable evolution there are a relative increase of erythroblasts in the bone marrow and diminution of the

leukoblasts. There are also eosinophilia and increase in the bone marrow of myeloid and histoid cells with eosinophil granules in different stages of maturation and increase of plasma cells. The authors say that the formation of erythroblastic tissue in the bone marrow is of good prognosis and that there is a relation between the modifications of the blood and of the hematopoietic organs in the course of pulmonary abscess and the etiology and evolutionary phase of the condition.

Differential Serologic Properties of Rickettsia Fever—According to Mariani, the serologic property that differentiates the classic form of typhus fever from other exanthematous fevers similar to typhus is its agglutinating property. The blood serum of patients suffering from typhus transmitted by the bite of lice agglutinates only *Proteus* X19. That of patients suffering from other rickettsia infections transmitted by ticks or fleas agglutinates only *Proteus* of the Kingsbury strain. Recently the author treated, in hospitals of Addis Ababa, several cases of typhus in white patients. The clinical picture of the disease was that of typhus. A scar showing the bite of ticks was not detected. In the largest number of cases the blood serum of the patients agglutinated only *Proteus* of the X19 strain. However, the blood serum of two patients agglutinated both the X19 and the Kingsbury strains and that of eight patients agglutinated only the Kingsbury strain. The author believes that typhus fever and exanthematous fevers probably exist in the Ethiopian plateau.

Genito-Urinary Disorders from Spina Bifida Occulta—According to Berri, spina bifida occulta is a frequent cause of genito-urinary disturbance in patients who are otherwise normal. He distinguishes three types of spina bifida occulta: a simple bony cleft without organic disorders, the bony cleft associated with lesion of the spinal cord, and a local process of abnormal formation of adhesions, ligaments and sometimes tumors which compress the spinal dura mater or the dural sac. Whereas a surgical intervention gives no relief to patients suffering from the second type of the disease, removing the compressing structures in the third type induces, as a rule, recovery or great improvement of the condition caused by compression of the spinal cord. The author's patient, aged 21 years, complained of nocturnal enuresis from childhood. His general condition, urinary tract and urine were normal. There were neither nervous diseases nor retention of the urine. Some times he suffered from frequent urination during the day. A simple x-ray examination of the vertebral column and also the examination of the structure after an ascending injection of iodized oil showed the presence of spina bifida occulta of the type of complete sacral hiatus. A deep cleft formed by the muscles that lay over the lesion was manifest from the beginning of the surgical intervention. There was a bundle of fibrous tissue in the muscles and over the unossified spot and cartilaginous tissues and strong adhesions replacing the spinous processes of the sacral vertebrae and entering deep into the spinal canal. The surgical intervention consisted in removing the block of fibrous and cartilaginous tissues and the adhesions and resecting the spinous process of the fourth lumbar vertebra which was the seat of formation of pathologic tissues.

Enuresis took place only twice during the first eleven nights that followed the operation. At the present time, five months after the operation, the patient, as a rule, feels, while sleeping, a desire to urinate, which wakens him. However, enuresis takes place once in a while. The urinary disorder was not entirely controlled. Compression of the dural sac, probably by adhesions that were not seen during the surgical intervention or by scar tissue that formed afterward, still persists. However, the improvement of the condition shows that the dural compression is less intense at the present time than it was previously.

Solitary Cysts of Long Bones—Salvati makes a general study of solitary cysts of the long bones in children, with especial reference to the type of cysts complicated by fracture of the cystic bone. Intense or slight trauma causes the fracture, which is followed by appearance of swelling of the cystic area, limitation of the movements of the limb and local pain. The cyst can be felt by deep palpation as a thickness or callus of the bone. As a rule there is some crepitation. The cyst shows in the roentgenogram as a multilocular or unilocular clear bulky area which is well delimited from the entire zone of normal bone. The periosteum does not react to the cystic formation. The bone that forms the cortex of the cyst becomes thin as an eggshell. The process of reparation of the fracture is complete within three or four weeks. Frequently it stimulates the process of ossification at the cystic area, but not to such an extent as to induce complete cure of the cyst. The author concludes that solitary cysts of the bone follow a long evolution for several years during which the bone may be fractured once or several times. When the fracture takes place, one may wait a reasonable time for a possible cure induced by the fracture. Otherwise a surgical intervention is indicated. The operation of choice is filling the cystic cavity with osteoperiosteal grafts, which stimulate the process of local osteogenesis and reparation of the bone. Three cases are reported. The patients were all 4 years old.

*Erythema of the Ninth Day (Milan) and Arsphenamine Dermatitis H Sprafke—p 333

Erythema of the Ninth Day and Arsphenamine Dermatitis—Sprafke says that the erythema of the ninth day was first described by Milan. It is an exanthem that develops approximately nine days after the injection of arsenicals in syphilitic patients. Milan observed morbilliform, scarlatiniform, rubeliform and urticarial types. The individual efflorescences of this exanthem are polymorphic. They may appear in small spots or may be roundish or star shaped. They are disseminated and may become confluent. The rapid disappearance is a characteristic of this type of exanthem. It may recur, the later attacks are usually mild but may also be extremely fulminant. However, Milan thinks that if the treatment is continued the erythema will generally disappear. The exanthem is preceded by prodromal symptoms that resemble those of infectious diseases (increase in temperature, sore throat, conjunctivitis and vomiting). Whereas a number of other investigators agreed with Milan on the symptomatology of the erythema of the ninth day, they did not agree with him on the interpretation of the symptoms. Milan believed that the cutaneous manifestations were true but mild measles, and so on in that the acquired immunity was temporarily interrupted or weakened by the treatment with the arsphenamine but that in the further course of the treatment, the immunity was reestablished. Milan cites a number of facts that he regards as corroborating evidence for his opinion. As the most convincing proof he considers the disappearance of the exanthems if the treatment is continued. By combining the erythema of the ninth day with the idea of biotropism Milan broke down the general belief that the appearance of an exanthem in the course of arsphenamine therapy is necessarily the precursor of an arsphenamine dermatitis. Since according to Milan the erythema of the ninth day and arsphenamine dermatitis are entirely different conditions it is important that

the two are differentiated so as not to deprive a syphilitic patient without cause of the most effective antisyphilitic remedy. After reviewing reports from the literature, which likewise stress the necessity of continuing the arsphenamine treatment in patients in whom the erythema of the ninth day appears, the author describes three cases of his own observation, which he detected among approximately 100 cases of syphilis.

Antigenic Characteristics of Vitamin D—Štefl points out that since the fundamental experiments of Much it has generally been known that many parenterally administered lipoids exert antigenic actions, that is, they stimulate the formation of antibodies. It was later determined by Sachs that chemically pure lipoids alone are capable of eliciting the formation of antibodies only in connection with heterogenic serum or protein. This antigenic action was later corroborated by a number of other authors, and today the appearance of a specific amboceptor in connection with a nonspecific complement is an essential foundation of many practical seroreactions in vitro. That at first experiments were made only in vitro is explained by the fact that, at the time of the discovery of the antigenic characteristics of lipoids, no lipoids were available that had sufficiently severe toxic effects to justify experiments on living animals. Since then however, a number of toxic lipoids have been discovered, for instance vitamin D and its group as well as the carcinogenic hydrocarbons. Nearly all the substances were sterols or sterol-like cyclic hydrocarbons. It was the author's aim to determine whether, by administering small doses of vitamin D in connection with heterogenous protein, it is possible to immunize an experimental animal against a subsequent fatal dose of vitamin D. He shows that the positive outcome of such a test involves the theoretical possibility of immunizing the organism against disorders that result from the pathologic accumulation of cyclic lipid substances in the body, whether the disorder is arteriosclerosis or carcinoma. The author made most of his experiments on white mice. He found that by administering vitamin D in connection with heterogenous protein it is possible to produce within narrow limits an immunity against the subsequent fatal quantity of vitamin D. Within the same narrow limits it is possible to produce a passive immunization with the serum of pretreated rabbits. The aqueous solution of vitamin D is about twenty times more toxic than the pure oily solution. Animals that are under the influence of vitamin D injections are much more sensitive to phenol than they are otherwise.

Irradiation of Spleen in Gynecologic Hemorrhages—Of twelve cases of juvenile gynecologic hemorrhages in which Caffier resorted to irradiation of the spleen, nine cases responded favorably, to be sure, in four of them the improvement was only temporary. However, in four of the five cases, in which the treatment was most effective not only was the hemorrhage arrested in from one to three days but the menstrual cycle became more regular. The author agrees with Horning, who believes that in the hemostatic mechanism of irradiation of the spleen a decomposition of thrombocytes in the spleen plays a part, but the author does not think that secretory factors are involved. Although the aforementioned cases of juvenile hemorrhages seem to suggest such an secretory effect, the failure

of irradiation of the spleen in many hemorrhages that were caused by hyperplasia disprove it. The author directs especial attention to the value of irradiation of the spleen in hemorrhages caused by myoma. He points out that the irradiation of the myomas often fails to produce prompt cessation of the hemorrhages, while the irradiation of the spleen quickly effects hemostasis, probably by increasing the coagulation ferment. In view of its rapid action, simplicity and harmlessness, he advises irradiation of the spleen for hemorrhages caused by myoma in patients in whom the removal of the myoma is contraindicated. Since the irradiation of the spleen produces only a temporary hemostasis, efforts must, of course, be made to exclude the cause of the hemorrhage. Irradiation of the spleen need not be restricted to cases of myoma but can be used also in refractory climacteric hemorrhages, provided the essential cause of the hemorrhage is excluded by other methods. The technic of the irradiation is simple. The author employs 180 kilovolts and 6 milliamperes and applies three tenths of the unit skin dose to a field 6 by 8 cm in the left hypochondrium, at a focus-skin distance of 40 cm.

Season and Diet in Habituation to Morphine—Amsler made animal experiments on morphine addiction in different seasons of the year and in the course of "acid" and "alkaline" diets. In experiments on guinea-pigs he found that during the spring and in the course of an acid diet the morphine habit developed in from two to two and one-half weeks, whereas during the fall and in animals receiving an alkaline diet from four to five weeks was required for the development of the morphine habit. In the breaking of the morphine habit the difference was not so great, but during the fall and during an alkaline diet the habit could usually be broken in from nine to twelve days, whereas it required from fifteen to eighteen days in the spring and during acid diets. Thus the results of these tests corroborate the expectation that in animals in which the tonus of the sympathetic nervous system is increased the forming of the morphine habit is more rapid and the breaking more difficult than in animals in which the tonus of the parasympathetic nervous system predominates. Since the calcium metabolism is influenced negatively by an acid diet and positively by an alkaline diet, it is suggested that calcium and vitamin D are important factors in the prevention and breaking of the morphine habit. In the conclusion the author points out that patients who have to be given morphine over longer periods should be put on an alkaline diet and, if necessary, should also receive calcium.

Actinomycosis Cured with Convalescent Serum—Although the combined administration of gold and specific vaccine had produced favorable therapeutic results in many cases of actinomycosis, Neuber nevertheless decided to try convalescent serum, having found the convalescent serum method highly effective in cases of erysipelas. He reasoned that the convalescent serum would be especially helpful in severe cases of actinomycosis in which the toxic condition makes active immunization and chemotherapy undesirable. He first resorted to convalescent serum in treating a patient who responded only slowly to the treatment with gold and specific vaccine. The intragluteal injection of 40 cc of convalescent serum produced a severe focal reaction, which subsided after three days. One week later the injection of convalescent serum was repeated. The reactions after this injection were much weaker, but the curative process was greatly accelerated. The author decided to try convalescent serotherapy also in patients who had received no other treatment. He describes several cases in which the convalescent serum produced favorable results but he admits that observations on a larger material will be required before a definite evaluation will be possible. He admits that in view of the comparative rarity of actinomycosis it might

prove difficult to obtain convalescent serum but thinks that this problem could be overcome by referring these patients to a central institute. But even in such a central institute the patients should be divided into two groups, one to be treated with gold and specific vaccine and the other with convalescent serum, for it has been observed that patients who have been treated with convalescent serum produce specific protective substances only in inadequate quantities, and the serum of such patients would not be so effective for use in other cases of actinomycosis.

 *Treatment of Morbus Maculosus Werlhoffii and of Other Thrombopenic Forms of Purpura C G Vervloet—p 3940

Treatment of Schizophrenia According to von Meduna—Kraus and his associates direct attention to the newer treatments of schizophrenia, particularly to the treatment of von Meduna, which is based on the theory of an antagonism between schizophrenia and epilepsy. Accordingly, von Meduna decided to induce epileptic attacks in patients with schizophrenia at first by means of oil of camphor and later by the intravenous injection of metrazol (a synthetic product of pentamethylene tetrazol, which is used like camphor). The initial dose for women is 4 cc of the 10 per cent solution of the camphor substitute and for men 5 cc. The patients are given two injections every week. The initial dose is given as long as it elicits attacks, if it fails to do so it is increased by 1 cc. The injections produce therapeutic effects only if they elicit the epileptic attacks. After pointing out that von Meduna produced favorable results with this treatment in fifty-four of a total of 110 cases the authors describe their own experiences with the method. They cite some cases in which it produced favorable results, others in which, after a temporary improvement, the psychosis exacerbated but after renewed treatment improved again. Then they show that numerous problems remain to be solved and that a definite evaluation of von Meduna's method is as yet impossible but that it nevertheless has considerable practical importance because in numerous schizophrenic patients it produces results that have been impossible heretofore. Early diagnosis is important and in cases of schizophrenia that have been recognized early either von Meduna's treatment or that of Sakel should be instituted.

Treatment of Hemorrhagic Purpura—Vervloet shows that in a case of thrombopenic purpura the intravenous injection of vitamin C had no immediate success but injections of liver extract and the oral administration of liver repeatedly produced prompt cessation of the hemorrhages. Fresh bone marrow from calves, when given in quantities of about 2½ ounces (70 Gm) daily, was found to exercise a strong therapeutic influence. In other cases the intravenous injection of calcium or the oral administration of calcium salts produced favorable effects. The efficacy of these widely differing therapeutic measures can be understood if it is considered that the mechanism of blood clotting is highly complicated. In some cases the action of several factors is required.

ACUTE ABDOMINAL CATASTROPHES

IRVIN ABELL, M D
LOUISVILLE KY

The surgical lesions occurring in the abdomen which may assume catastrophic proportions are many, the term "acute conditions of the abdomen" has been employed to designate the group urgently demanding surgery for their relief. Many of them present symptoms of such similarity that preoperative clinical diagnosis becomes a matter of difficulty and at times accurate distinction between them is quite impossible. The common indication in such lesions is surgical relief, this being true, it is apparent that the first duty of the physician in a given case is to determine for or against its employment.

The rapidity with which the disastrous changes in the abdomen develop make it imperative that this determination be made at a time that gives the patient the greatest chance for recovery. Regarded in this light the final differential diagnosis of the cause, though of the utmost importance, must take second place if the mortality from catastrophic lesions is to be diminished. To open the abdomen in a patient presenting acute symptoms and on examination find that the operation was unnecessary is admittedly bad surgery and an admission of diagnostic failure, in condoning such a mistake it is submitted that the mortality of the group of lesions under discussion will not be lowered unless one is prepared to perform a laparotomy without waiting for a detailed diagnosis and willing to risk an unnecessary one rather than disregard the suspicious signs that may indicate the early and immediate stage of a condition convertible by delay into a disaster.

APPENDICITIS

A survey of hospital statistics reveals that appendicitis is responsible for fully 50 per cent of emergency abdominal operations. Typical cases of this disease seen early present no problem either in diagnosis or treatment. The fact that the mortality from this disease has shown a yearly increase from 11,000 in 1920 to more than 20,000 at the present time is conclusive evidence that patients afflicted with it do not come under observation or at least to surgical treatment at a time when its relief is a simple procedure. Self medication and ignorance regarding the significance of abdominal pain on the part of the public combined with procrastination and difficulty in the recognition of atypical cases on the part of the profession bring about the problems which delay in the institution of appropriate treatment entails. With a normal embryologic

development the appendix comes to rest at what by common usage is designated McBurney's point. Three variations from the normal allow the appendix a wide latitude in location, it being found in every part of the abdomen except the left upper quadrant, these are, first, a failure of rotation of the cecum, which, depending on its degree, places the organ at any point along an arc extending from the midpigastrium to the liver and thence downward to the right iliac fossa, second an unusually long mesocecum, giving to the cecum a wide circle of mobility, and, third, the rare anomaly of transposition of the viscera. The atypical situations of the appendix becloud the diagnosis in the event of its inflammation, one's attention naturally being directed to the organs normally found in the respective localities mentioned. Other causes of delayed recognition are presented by the deviation of symptoms when the situation of the appendix is retrocecal, particularly when there is an absence of the meso-appendix, the organ being practically extraperitoneal, and when, owing to a long mesocecum, it is located in the pelvis, the absence of localized tenderness and rigidity may lead to delay while the sequence of pathologic events in the appendix remains unchanged. The sequence of symptoms consisting of pain, nausea, vomiting, fever and leukocytosis should put one on guard and direct suspicion to an atypically situated appendix when such symptoms cannot be definitely ascribed to an organ normally located at their point of origination.

Recognition of appendicitis during infancy and childhood is not always an easy matter, the symptoms are the same but the child is not a miniature adult, it lacks cooperation, the blood count shows wide fluctuations and until about the fourth year constantly shows a relative lymphocytosis, the disease here, as in the opposite extreme of life, is prone to run a rapidly destructive course. Muscle spasm is elicited with difficulty, and tenderness frequently can be best elicited on rectal palpation. When, from whatever cause, delay has allowed the development of gangrene, spreading peritonitis or diffuse suppurative peritonitis to develop, problems are presented on which there is a wide diversity of opinion. Time forbids an analysis of the arguments, results and statistics of the proponents of the immediate and the delayed operation, the type of operation and the question of drainage. My practice has been and is to regard such conditions as emergencies, not that the patient should be subjected to operation immediately on arrival at the hospital, since peritonitis does not spread with such rapidity as to forbid restoration of fluid chloride and glycogen balance before operation is undertaken but that removal of a depot of necrotic, virulently infected tissue, accomplished gently without undue trauma to exposed peritoneal surfaces under spinal ethelene or cyclopropane anesthesia, with or without

drainage as the case demands, not only meets the pathologic indications but in my experience has afforded the best chance for recovery

OBSTRUCTION

Intestinal obstruction continues to cause a mortality which is a serious indictment of both diagnostic ability and surgical initiative. It is common knowledge that while acute intestinal obstruction carries an inevitable mortality, the greater proportion of it may be justly attributed to delay in recognition and to tardiness in the institution of appropriate treatment. The most important single factor is the element of time, a second one of great moment is offered by the site and character of the obstruction, whether high or low, the former pursuing a more rapidly fatal course than the latter. The research workers by their physiochemical studies of the body fluids have afforded much valuable aid in the appreciation of the changes in body chemistry with the indication of means to assist in the restoration of the latter, but the underlying fact, with which all adjutants must be correlated is that the obstruction is mechanical and must needs be corrected mechanically. The solution of the problem in the early hours when but simple obstructions are present may require nothing further, with the incidence of the complications dependent on strangulation and toxemia, which invariably follow the continued presence of obstruction, the relief of the obstruction becomes but one of the indications to be met and the risk of any operative procedure is enormously enhanced. The external obstructions in the shape of strangulated hernias present not only the classic symptoms but give visible evidence of their presence and hence do not offer any problem in recognition. The internal obstructions are hidden from view and are obscure to palpation, to await the onset of symptoms which afford indisputable proof of their presence in an effort to make a differential diagnosis is but to lose invaluable time in combating the approach of dissolution. The presence of abdominal pain, nausea, vomiting and constipation with an absence of fever and leukocytosis should put the burden of proof on the attendant to show that no obstruction exists. The history, particularly if previous abdominal ailments or operations are indicated, the physical examination showing the presence of active peristalsis visible or audible, with a flat roentgenogram competently interpreted with reference to fluid levels and distribution of gas, in addition to the three cardinal symptoms of pain, vomiting and constipation will permit of a diagnosis before the accession of fever, leukocytosis, distention, paresis and profound blood changes indicate the patient's condition to be one of extreme gravity.

The preparation of such patients is most important and will depend on their condition on admission to the hospital, when the patient is dehydrated, lost fluids and chlorides are to be replaced, and when debilitated, resistance increased by transfusion before operation is undertaken.

The type of operation must be suited to the local lesion and to the patient's condition, release of obstructing bands and adhesions, resection of tumors by the one or two stage methods, resection of gangrenous intestine with end to end anastomosis or exteriorization as a shotgun barrel enterostomy, enterostomy above the obstruction alone, or combined with the removal of the latter, all find their place in the various phases and stages of obstruction. Intussusception is characterized by symptoms which rather readily distinguish it from

other forms of obstruction, namely, age incidence, bloody stools and a palpable mass. The common or ileocolic variety is seen in infants, the rarer colocolic is occasionally observed during childhood, and a still rarer variety may be noted at any age and at almost any point of the intestinal tube as the result of perverted peristalsis dependent on an intra-intestinal neoplasm. It seems trite to state that diagnosis should be made on the three cardinal symptoms mentioned before distention beclouds the picture, and appropriate treatment applied before gangrene renders difficult or impossible its successful accomplishment. When confronted with evidence of obstruction, it may be well for one to remember that during infancy intussusception is the common cause, that during early adult life hernia and peritoneal adhesions are responsible for the majority, while in late adult life carcinoma becomes the greatest causative factor.

ULCER

The complications of peptic ulcer urgently demanding treatment are hemorrhage and perforation. Hemorrhage rarely presents as an emergency requiring operation for its control but does at all times call for urgent and appropriate treatment, occasionally being of such massive extent as to lead to an immediate fatality. Acute perforations give rise to agonizing pain with coincident nausea and vomiting, the abdominal musculature assuming a boardlike rigidity. Primary shock may be present or absent, when primarily absent or the patient is seen during the stage of reaction, a normal temperature and pulse may lull one into a sense of false security. Delay in diagnosis and treatment at this stage is but to invite disaster, with the appearance of symptoms indicating a spreading peritonitis, the favorable time has passed and the grim specter is in the offing. With or without a history of digestive disturbance indicating ulcer, the sudden onset of pain, the tenderness and rigidity of the abdominal muscles, the shallow, costal type of respiration, the tenderness of the pelvic peritoneum when elicited and the presence of gas as shown by the flat x-ray film should enable one to make an early diagnosis. My experience with acute perforations doubtless parallels that of other surgeons, I have lost no patient operated on within six hours after perforation and have saved but one operated on twenty-four hours or longer after perforation, within these time limits the mortality shows a progressive increase with each added hour of delay. Closure of the opening with superimposed layers of Lembert sutures and an omental fat graft suffices not only to control leakage but in a goodly percentage to secure healing of the ulcer as well. The employment of additional measures such as excision or cauterization of the ulcer, pyloroplasty, gastroenterostomy or resection of the stomach will depend on the extent, character and location of the local lesion and the general condition of the patient. The prime consideration in such catastrophes is the saving of life, this is accomplished by the stoppage of the leak. It may be stated as a general rule that the greatest safety to the greatest number prohibits doing more, yet in the presence of marked pyloric or duodenal obstruction, granting that the condition of the patient permits, additional measures may be undertaken with reasonable safety, giving assurance of relief and obviating a second operation.

DIVERTICULITIS

Diverticulitis occurring in Meckel's diverticulum and obstruction having its origin in the various forms of this vestigial remnant have been long recognized.

occasional causes of acute abdominal catastrophes, during the present century diverticula in other portions of the intestinal tract have come to be known as acting in a similar capacity, while hemorrhage and perforation complicating peptic ulcer in Meckel's diverticulum are being reported with increasing frequency. None of the symptoms dependent on the presence of diverticula and their complicating disease, with the exception of those at the pharyngo-esophageal junction, are pathognomonic and a differential diagnosis cannot be made on clinical evidence alone. Diverticula other than Meckel's are readily revealed by the x-ray film but it is not always advisable to employ the barium sulfate meal or enema in the presence of their disastrous complications. The symptomatology of the inflammatory lesions of Meckel's diverticulum and of single diverticula situated elsewhere closely mimics that of the appendix and oftentimes clinically is not distinguishable from it, consisting of pain, nausea, vomiting, localized tenderness and rigidity with an increased leukocyte count. The complications readily convertible into catastrophes are acute diverticulitis, suppurative peridiverticulitis, perforation with diffuse peritonitis and obstruction. Their surgical treatment does not differ from that of similar pathologic lesions dependent on other causes.

PANCREATITIS

Acute pancreatitis is an infrequent cause of abdominal catastrophes, being responsible for less than 1 per cent of such cases. Its rarity and the similarity of its symptoms to those of perforated peptic ulcer and of gangrenous and perforative cholecystitis and in its later stages to those of intestinal obstruction account for the infrequency of correct preoperative diagnosis. Clinically it appears as acute pancreatic edema, acute pancreatic necrosis, acute hemorrhagic pancreatitis and pancreatic abscess, which are not separate clinical entities but represent different stages of the same process, the origin of which is not entirely clear. There are no pathognomonic symptoms, the most important encountered being pain, vomiting and collapse. Laboratory examinations are not of great aid in reaching a diagnosis, the white cell count in our series of thirty-one varied from 5,300 to 26,000, the urine in all showed albumin, none showed sugar, bile, casts, microscopic pus and blood were noted. The liberation of the pancreatic ferments leads to an increase in the amount of diastase in the blood and urine, the urine normally contains from 10 to 20 units of diastase, in acute pancreatitis this may be increased to 100 or 200 units, constituting a reliable corroborative symptom when laboratory facilities for its determination are available. Previous history of gallbladder disease, pain radiating from the right costal margin across the upper part of the abdomen, tenderness following the course of the pancreas, pain and tenderness to the left of the upper midline and detection of a mass in the pancreatic area are beacon lights when elicited. After all it is not so important to make a correct diagnosis of acute pancreatitis as it is to make a diagnosis of an acute surgical lesion in the upper part of the abdomen, the predominance of symptoms at and above the umbilicus will usually permit of their localization, when prompt operation will direct one to the pathologic condition. The indications are to relieve tension, to stop hemorrhage, to prevent leakage and to afford drainage. Auxiliary measures directed to the gallbladder and common duct when the condition of the patient permits, are useful procedures in promoting recovery and securing immunity from further attacks.

RUPTURED ECTOPIC GESTATION

A ruptured ectopic gestation offers a dramatic picture which should give but little difficulty in interpretation. It seems to me that in the future the aim of the profession should be to prevent this complication by making an effort to recognize and remove an ectopic gestation before its rupture. Rupture of the sac is accompanied by sudden abdominal pain, at times vomiting, usually faintness, anemia and collapse, the pulse is rapid, of small volume and the temperature is subnormal. The abdomen is tender but not rigid, vaginal examination reveals a tender pelvis with or without a palpable mass and at times percussion will reveal free fluid in the abdomen. Severe hemorrhage from a ruptured graafian follicle gives a similar clinical picture, but the accompanying evidences of pregnancy are lacking, indications for treatment in the two conditions are identical. It has been argued in some quarters that death from hemorrhage does not occur and consequently that cases of ruptured ectopic gestation should be treated expectantly until full recovery has occurred from the primary shock and depression. It is readily admitted that in some cases the shock and depression are out of all proportion to the direct blood loss, clearly indicating that in such cases factors other than hemorrhage play a rôle and that delayed operation in such instances may lessen the hazard to the patient. It is further admitted that, if at the time the patient comes under observation there is evidence of cessation of bleeding, delayed operation may again be advantageous. On the other hand, it is submitted from personal knowledge that patients do die from primary hemorrhage, it is further submitted that it is impossible to distinguish on clinical signs alone the case in which the alarming symptoms are largely due to shock from the one in which they are largely due to hemorrhage. The blood count cannot be relied on for an accurate estimate of blood loss because of fluid concentration, hence unless the lapse of time since the onset of symptoms and the condition of the patient plainly indicate that cessation of bleeding has occurred, it has been my practice to rehabilitate the patient with transfusion and to do an immediate operation.

CHOLECYSTITIS

Acute cholecystitis furnishes an instance of the acutely involved abdomen about the proper treatment of which there is as yet no unanimity of opinion. Typical cases are readily recognized, the atypical ones as readily confounded with appendicitis, leaking peptic ulcer and pancreatitis. Difference of opinion arises when the question of their consideration as surgical emergencies is approached, gangrene and perforations readily fall within this category, but the advisability of early or of delayed operations in acute inflammations of the gallbladder finds both proponents and opponents. To review the arguments for and against and to survey the statistical results are beyond the scope of this paper. My own belief and practice is to place the acute obstructive type of cholecystitis in the emergency class, since 95 per cent of all cases of gangrene and perforation occur in this group. The infectious type of cholecystitis without obstruction does not carry with it much threat of these complications, both empyema and hydrops are chronic obstructive lesions and are relatively free from such dangers and hence offer some basis for the arguments of those who would place them in the elective group. With coincident blockage of the cystic duct and the presence of active infection in the gallbladder, delay only too often invites the appearance of complications.

which not only enhance the danger to the patient but increase the technical difficulty of a subsequent operation. Gangrene, perforation into the liver with the formation of a hepatic abscess, perforation through the free surface with resultant diffuse peritonitis, or if walled off by adherent adjacent viscera, the production of a subhepatic abscess, cholangitis, hepatitis and pancreatitis all follow in the wake of acute infection in an obstructed gallbladder, their prevention by early operation will give both a lower morbidity and a lower mortality than the expectant plan of treatment with delayed operation. To consider them as emergencies does not prohibit the expenditure of some hours in buttressing the liver with dextrose, in correcting the deviations in body chemistry and in restoring the proper balance in body fluids.

COMMENT

While it is vitally important to recognize and act on symptoms urgently indicating surgical intervention in acute abdominal catastrophes, it is equally important to appreciate the source of threatening symptoms caused by conditions not amenable to surgery. A good general rule is to regard the presence of pain, nausea, vomiting and constipation for as long as six hours as indicative of an intra-abdominal surgical lesion until proved otherwise, while the absence of constipation and the presence of diarrhea usually betoken medical rather than surgical illness, they cannot be accepted as positively excluding the latter. A well taken history combined with a complete physical examination and an analysis of the blood and urine should be given every patient presenting acute abdominal symptoms, by so doing one may hope to avoid the pitfalls in diagnosis in differentiating between surgical lesions and medical ailments which simulate them. Among the latter to be borne in mind are the abdominal crises of lead poisoning, the gastric crises of tabes dorsalis, diabetic acidosis, diaphragmatic pleurisy and incipient or central pneumonia, coronary thrombosis, renal and ureteral calculi and lesions of the female pelvic organs, particularly salpingitis in unmarried girls. All of these should be rather readily recognized on a careful diagnostic study.

321 West Broadway

ABSTRACT OF DISCUSSION

DR FRANK H. LAHEY, Boston. I don't know any subject that needs stressing more than the subject of acute conditions of the abdomen, and I don't know any one better qualified to do it than Dr. Abell. I should like to bring out a few additional facts. One is the question of peptic ulcer hemorrhage. Surgeons, and certainly gastro-enterologists, easily get the point of view that the undesirable time to operate on a patient with a gastric or duodenal hemorrhage is when he has a hemorrhage. That is the time when the vascular balance is upset, when the patient is easily shocked, and when relatively extensive operative procedures must be undertaken. There are two types of hemorrhage from ulcer, one which will cease spontaneously, which is repeated only once or twice, and the other type of repeated massive hemorrhage which has gone on and in a certain number of cases will go on to a fatality. Here can be displayed the highest degrees of surgical judgment and diagnostic acumen in selecting the type for surgical intervention because here the hazard is tremendous yet justifiable. In the patients going progressively downhill, with repeated hemorrhage, even though the mortality is 50 or 60 per cent, it is justifiable to open the abdomen and inspect a duodenal ulcer to see whether or not it can be removed by radical pylorotomy. This is a horrid operation to look at, a tearing out of the duodenum, but the bleeding vessel can be tied and can be controlled. At times the patient

will not stand this procedure and it is justifiable to incise the pylorus, demonstrate the ulcer and transfuse it with silk and do a gastro-enterostomy. I don't know what there is about a rectal examination, but the doctors don't like it and neither do the patients. I have made more mistakes by omitting a rectal examination than by the omission of any other diagnostic feature in connection with abdominal diagnosis. Here the pelvic abscesses, here the pelvic appendices hanging in the pelvis, that do not show through abdominal palpation, can often be demonstrated. Here many a patient with a carcinoma of the stomach which seems operable will be found to be inoperable by the demonstration of the nodules of malignancy in the pouch of Douglas. The question of uterine pregnancy can be settled very simply without an abdominal operation. The patient can be put up in stirrups and a simple vaginal puncture will demonstrate the presence of blood in the pelvic cavity. Dr. Abell has mentioned Meckel's diverticulum. The necessity of searching for regional ileitis should be kept in mind, and it is important that gastro-enterologists should urge radical removal of this lesion on their surgical friends, lest they become too conservative. In my hands, resection has been done in sixteen out of nineteen of these cases, and all the patients are well. Whenever I have done the conservative operation, I have been sorry. Given regional ileitis, resection, provided the patient's condition will permit, is, I believe, by far the best procedure. The more experience I have with acute cholecystitis, the more I lean toward immediate operations and total removal when it can be done with safety.

DR ROBERT LEE PAYNE, Norfolk, Va. Most of the cases present acute problems and the patients are so desperately sick that diagnosis is often impossible. The first practical point is the blood count. In most of these cases I find that the total white count is low, indicating more or less embarrassment or toxic paralysis of the activity of the bone marrow, and a high neutrophil count. The practical point is to determine the presence of toxic granulation in the neutrophil. If there is a marked toxic granulation in the neutrophil one may be reasonably sure that the patient's resistance is extremely low and that the possibility of doing something for him is very bad. The next point is the use of morphine. The common knowledge prevails that morphine is given these patients before they come to us, thus making the diagnosis obscure. In the evaluating of symptoms such an abdomen presents, there are two reflexes to consider, the central reflex to the brain and the spinal reflex. The spinal reflex cannot be obliterated by morphine, but the central reflex of pain for the higher centers can be if one will study these patients for a few minutes most carefully and get in one's mind a fixed picture of what that abdomen shows and then give the patient sufficient morphine, one fourth, one half, three-fourths or even 1 grain, to obliterate completely the higher sensory reflexes to the brain, one can often go back in thirty minutes and go over that abdomen and define accurately the location of the lesion. The author has said that our principal responsibility is to afford surgical relief in these cases. It is equally important to know when not to operate, because surgery is often deprecated in the mind of the layman when so many of these patients die, because they were operated on as a last resort. My experience has taught me that if a correct diagnosis cannot be made beforehand one may expect about a 50 per cent increase in mortality over those cases in which a correct diagnosis can be made. A word about cholecystitis. In an analysis of 355 cases, I found sixty-five classified as real, acute cholecystitis and of these twenty-nine were gangrenous. The mortality in these twenty-nine cases after cholecystectomy was two, or 10 per cent. If there are going to be twenty-nine gangrenous gallbladders in sixty-five acute cases of cholecystitis, it is clearly indicative of the fact that these cases come into the surgeon's care too frequently at a late stage.

DR HARVEY B. STONE, Baltimore. Dr. Abell's opinion that a prompt operation in most of the various phases of acute appendicitis is advisable seems to me the wise principle to adopt particularly when qualified by his advice as to measures for rehabilitation of the patient's general condition, and skill and gentleness in technic. The author's emphasis on the

necessity for prompt and early operation in acute mechanical intestinal obstruction strikes a most responsive chord also. The administration of intravenous fluid, salt and dextrose and the decompression of the upper alimentary tract by catheter and suction have proved great aids in the treatment of obstruction, but their very value has had a tendency, which I regard as dangerous, to cause them to be considered reasons for deferring operation. They are accessory measures that should be instituted before, during and after operation, but the essential treatment of the condition is the prompt surgical relief of the obstruction itself. There has recently developed a feeling with regard to acute pancreatitis that some modification should be made in the accepted treatment which Dr Abell has set forth in his paper. This view holds that the fulminating cases cannot be helped by drainage or any other surgical procedure, and the less intense forms of the disease, if let alone, may subside into a state at which later operation is helpful but may be accentuated by premature surgical intervention. A certain amount of clinical evidence is adduced to support this position. The statements of Dr Abell about perforated peptic ulcer, diseases of diverticula and ruptured ectopic pregnancy present a clear and sound surgical view of these catastrophes, and, while individual opinions may differ on some details, his summary represents accurately the present prevailing ideas. His comments on the treatment of acute conditions of the gallbladder is particularly pleasing to me, as I have for some years been a convert to the prompt operation school of thought in this group of lesions. Of great importance is the emphasis he has placed on the necessity to think of, examine for and, if possible, exclude conditions that may mimic surgical disasters. As surgeons grow in experience and judgment, they become increasingly reluctant to operate without concrete and convincing reasons. The surgical beginner, tortured by the quite conscientious fear of concealed damage rapidly growing worse, may feel forced to explore an obscure case in which a more mature surgeon, estimating all the elements of the situation, including the general condition of the patient, will feel safe in waiting longer in the hope that the uncertainties will clear up.

DR SAMUEL MOREIN, Providence, R. I. This comprehensive paper and the points brought out by the discussion bring to mind the seriousness of the diagnosis of an acute abdominal emergency which may become a catastrophe. I have in mind spontaneous pneumothorax. This condition does not frequently present symptoms of an acute abdominal emergency, however, on occasion it may. Given a patient with symptoms of dyspepsia of many years' duration with a positive diagnosis of peptic ulcer and lacking any previous history of pulmonary disease an emergency call from him presenting symptomatology of an acute abdominal condition and no symptoms with reference to the chest will lead one to assume that a perforated peptic ulcer exists. Recently I had occasion to see two such cases. In both there were practically no symptoms with reference to the chest and what saved these two patients from unnecessary surgery and possibly saved their lives was that further attention was paid to the chest before calling a surgeon. X-ray examination, merely a flat plate, disclosed a spontaneous pneumothorax on the right side in each instance. A little conservatism had meant the saving of the lives of these two patients. I agree with Dr Lahey that more rectal examinations may mean the saving of these patients from unnecessary surgical intervention. In my opinion a more frequent use of the stethoscope also, instead of centering entire attention on the abdomen, not overlooking the fact that the X-ray examination is important, will supply valuable information.

DR HIRSH I. GOLDSTEIN, Camden, N. J. I wish to report the occurrence of massive bleeding from the stomach in two patients, of the same family, neither of whom required surgical intervention for their repeated hematemesis or gastrorrhagia (telangiectatic gastrostasis or bleeding due to gastric telangiectatic dysplasia). These patients gave a history of the usual hereditary epistaxis and widely scattered telangiectatic lesions similarly affecting many members of the family. In one of these patients telangiectases were seen proctoscopically.

These patients should never be operated on for the bleeding. They are similar to those reported by Dr Abell. Injections of moccasin snake venom and the oral administration of solution of Russell viper venom, with small blood transfusions when necessary, are helpful in these cases. The second matter to which I wish to call attention concerns the records of two fatal cases of terminal or distal ileitis, "Combe-Saunders-Abercrombie's disease," or what has in the past five years been referred to as "Crohn-Ginzburg-Oppenheimer's distal ileitis," if an eponym is to be used for this definite clinical entity. On July 4, 1806, before the Royal College of Physicians, of London, Charles Combe and William Saunders reported a typical fatal case of terminal ileitis with 2 or 3 feet of the intestine involved, under the title "A Singular Case of Stricture and Thickening of the Ileum." John Abercrombie (1780-1844) reported a case in a girl, aged 13, with about 18 inches of the lower end of the ileum involved. The lungs and all other viscera were healthy. If we are to continue to use an eponym for this clinical entity, let it be Saunders-Abercrombie-Crohn's disease.

DR M. G. WOHL, Philadelphia. There is one phase in the diagnosis of acute abdominal catastrophe that should be stressed. There are patients with metabolic disturbances who may present abdominal symptoms which will often mimic intra-abdominal lesions. I refer particularly to the acidosis of diabetes mellitus, in which condition the nausea, the vomiting, the abdominal soreness and even the leukocytosis and fever will often prove confusing in a differential diagnosis. In hyperthyroidism patients may likewise exhibit acute attacks of vomiting, and abdominal pain which may erroneously be construed as due to an acute intra-abdominal surgical lesion. Drs W. E. and H. F. Robertson and I recently reported three such cases that came under observation at the Philadelphia General and Temple University hospitals, in which the abdominal symptoms were so severe as to suggest a surgical abdominal catastrophe. One of these patients, after several consultations with one of the leading surgeons in Philadelphia, was operated on for an appendiceal abscess. A normal appendix was found. A second patient at postmortem failed to show any abdominal pathologic condition to account for the severe abdominal symptoms that were interpreted as a surgical abdominal catastrophe. It is worth emphasizing that in an acute abdominal catastrophe, if the patient is known to be a victim of a metabolic disorder, the abdominal symptoms may be referable to this metabolic condition rather than to a surgical lesion. If this is borne in mind, the grave risk of an unnecessary exploratory operation in such patients will be avoided.

DR JOHN FALLON, Worcester, Mass. I have a minor suggestion for the diagnosis of extra-uterine pregnancy. The patient with extra-uterine pregnancy who comes in during a massive hemorrhage is not an especial diagnostic problem. The woman entering for acute abdominal symptoms, with a history of something that may or may not have been a hemorrhage a few days before, is the puzzle. My colleague Dr J. J. Dumphry and I have found an increased van den Bergh reaction in two thirds of about fifty patients seen in this stage, that is, if enough hemoglobin has been broken down and reabsorbed from the pelvis, the blood bilirubin is appreciably raised.

Garrison and Music.—No matter on what subject Garrison was writing, somehow he had to bring in music and then of course Brahms. His countless editorials and articles are full of excursions into the field of music. Garrison's skill in bridging history with art is to a large degree responsible for the distinctive, rich style of his writings. His prose often attains rare beauty and sweeping forcefulness. There can be found sentences in his writings which "compass the whole inner rhythm of life and passages which take the reader on a whirlwind tour through the arts of all ages. Then again there are charmingly loquacious reflections of a resigned, sadder but wiser man. Dull and dry he never could be.—Tietsch, F. L. The Colonel Played the Piano, *Bull Hist Med* 5:360 (April) 1937.

EXPERIENCES IN THE INSULIN-
HYPOGLYCEMIA TREATMENT
OF SCHIZOPHRENIA

D EWEN CAMERON, M.D.

AND
R G HOSKINS, M.D.

WORCESTER, MASS

Schizophrenia, by reason of the incapacity which it produces and by reason of the fact that it is essentially a chronic disease with a comparatively low direct mortality rate, is one of the most serious disorders, both from the individual and from the economic point of view. The actual expectation of schizophrenia in the general population is not high, amounting, according to Sjogren,¹ to from 0.38 to 0.98 per cent. The admission rate is in the neighborhood of 25 per cent of all first admissions to mental hospitals. From 1917 to 1934 in the state of Massachusetts² the percentage fluctuated from 20 to 27.8. Because of the chronicity of the disorder, however, schizophrenic patients occupy one fifth of all the hospital beds in the United States, reckoning in general hospital as well as in mental hospital beds.³

The spontaneous remission rate has been variously computed at from 20 to 40 per cent. Factors that have a bearing on this variation are the length of time on which the calculation is based and also whether the cases were early ones coming to clinics or later ones coming to mental hospitals.

In view of the fact that therapeutic procedures are most efficacious when applied early, it is important that the onset of the disorder be promptly recognized. This is often insidious. A common early symptom is a growing loss of social interest, the patient preferring to stay at home rather than go out and "mixing." There is growing indifference to the people about him and toward his former interests. Undue suspiciousness may appear, as when the person begins to feel that others do not care for him or that they are talking about him. There may be gradual failure in work, resulting partly from growing indifference and partly from failure in concentration. The latter symptom is one of which the individual himself often complains, saying that he can no longer follow out his train of thought or that he cannot keep track of what he has been reading. Odd mannerisms or ways of acting may appear and these seem to cause the patient very little concern. There may be undue worrying over his physical condition, and this is especially suspicious when the complaints are unusual and unlikely. These complaints often go together with statements by the patient that he feels he ought to build himself up by means of dieting and exercise. Less frequently one notes the appearance of new interests which seem to be out of line with the patient's personality, such as sudden religious activity, sudden interest in rather unusual topics such as philosophy and metaphysics, and sudden determinations to cut himself off from the world and to be especially pure and apart from others.

The Eli Lilly Company of Indianapolis gave generous supplies of insulin.

Agents have been found in recent years that will produce marked ameliorations, but the improvements have been, for the most part, very fleeting. In 1933 Manfred Sakel⁴ introduced the insulin treatment of schizophrenia. He claimed exceptionally high recovery rates. He stated that in early cases, and by this he meant cases in which not more than six months had elapsed since the first changes were noted, it was possible to produce full remissions in 70 per cent. In addition, he asserted that a further 18 per cent could be sent home fit to carry on their work although not fully restored to health. Since that time further series of cases have been reported by Sakel⁵ and Dussik and Sakel,⁶ by Muller⁷ in Switzerland, by Benedek⁸ in Hungary and by Berglas and Sušic⁹ in Czechoslovakia. All these workers report very high remission rates, the majority of them being as high as those reported by Sakel. Various smaller series have been produced, the majority of which have also given favorable results.¹⁰ We began the use of the Sakel method in March 1936. It is interesting to note that there is a higher proportion of unfavorable or guarded reports by writers whose series are small, a fact which suggests that experience is an important factor in obtaining the best results from this technique.

CASE MATERIAL

Six of our cases were selected as old ones, none of them being of less than four years' duration. The remaining nineteen cases were chosen as representing the most recent cases available. In seven cases symptoms were of less than six months' duration and in the remaining twelve cases symptoms had been present for from one-half to three years. Six of our subjects were women. No case was accepted in which there was any suspicion of cardiac, renal or pulmonary disorder. The age distribution was from 13 to 42 years. No attempt was made to select on the basis of reaction type or on probability of recovery. Our experience in the latter regard has been that the correlation between prognosis recorded at the time of admission and subsequent progress is almost negligible.

TECHNIC

Treatment consisted in giving insulin, 20 units, subcutaneously to the fasting patient. In some cases this was given daily and in a few twice daily. The dosage was raised by from 2 to 10 units until a clear-cut hyperinsulin reaction was produced. Thereafter the dosage was dependent on the progress of the patient. In the majority of cases dosage was increased until coma was produced. We have followed Sakel's technique closely. Our only deviation has been in a greater utilization of intravenous dextrose in terminating the insulin reaction. After extensive comparison of this method with that advocated by Sakel, namely, the administration of sugar

by nasal tube, we have been unable to note any considerable advantage in the use of the latter

The earliest symptoms of hypoglycemia usually set in within half an hour and consist in a slight drowsiness, which may increase to actual sleep. About this time or a little later some sweating appears, which later may become copious. This, together with the fact that the heat regulating mechanism appears to become impaired, sometimes results in low body temperatures. Consequently, it is necessary that the patient should be kept adequately covered. It is of interest that in spite of the low temperatures we have never noted shivering or gooseflesh save on two occasions when the patient was tending to come out of hypoglycemia spontaneously. On the other hand, shivering often sets in within a few minutes after the giving of sugar, suggesting that the heat regulating mechanism has returned to normal functioning.

At the end of from one to three hours the drowsiness begins to pass over into increasing wakefulness, which may again, after one-half hour or so, pass over into drowsiness, which in turn leads directly into coma. This usually is achieved by the third to the fifth hour after treatment is commenced. On the other hand, the excitement may become very severe and the patient's delusional ideas may become much more vivid. Excitement of this type, too, may subside into drowsiness and coma, but in a certain proportion of cases it becomes so severe and exhausting that treatment has to be terminated.

Just prior to the commencement of coma, twitching and jerking of the face and of the limbs are common. Occasionally this jerking may become increasingly severe and lead on to convulsions. It is to be noted here that, contrary to the usual textbook descriptions, convulsions when the patient is in coma are very much rarer than they are when he is on the point of entering coma.

We usually consider somewhat arbitrarily that coma is present when the patient can no longer swallow—when, if he is turned on his side, saliva tends to drool from the mouth, or when, on the eyelids being drawn up, the eyeball is found to be wandering slowly in the orbit. The pulse, which tends to increase in frequency up to the time of coma, begins to fall somewhat as coma progresses but rarely falls to the pretreatment level. The same is true in general of the blood pressure. Coma may be prolonged for varying periods from ten minutes up to about one and one-half hours, but the total duration of the treatment should not exceed five hours, as there is a very considerable danger of irreversible brain changes occurring if hypoglycemia is allowed to persist. A mishap particularly to be guarded against is to allow hypoglycemia to become reestablished while the patient is asleep and remain undetected until the following morning.¹¹

Treatment can readily be terminated by the giving of carbohydrate. When it is desirable to terminate it before the onset of coma, the patient drinks a sugar solution and then takes a high carbohydrate meal. When the patient is in coma, treatment may be terminated either by the administration of 200 Gm of sugar by nasal tube or by means of intravenous administration. On the whole nasal administration is preferable save when speed is indicated. Within a minute after the intravenous injection of from 50 to 100 cc of 25 per cent dextrose the patient is more or less

completely aroused and within five minutes may be up and walking about. It is a useful precaution to have the needle attached not directly to the syringe but by means of a piece of rubber tubing about 5 inches long. In this way, should the patient be jerking, there is less chance of the needle being pulled out of the vein. Nasal administration results in the patient coming out more slowly and he may not be fully roused for one half to three quarters of an hour. Whatever route is used, it is of the utmost importance that the patient should immediately be given a meal. Otherwise the sugar given may be burned up and the patient pass back into hypoglycemia.

It has been noted that the giving of sugar may actually increase the intensity of the hypoglycemic symptoms. We have observed indeed in cases in which treatment was terminated before coma that the mere sight of the sugar solution being brought to the patients to drink has on occasion produced an increase in sweating or has provoked it when it was not present. On several occasions, too, we have noticed that the patient has gone rapidly into deeper coma after a nasal administration of sugar. These intensifications usually last only a matter of minutes.

The essential principle of the treatment, as far as it is at present understood, consists of the fact that in general the mental state in which the patient finds himself at the time of termination of treatment tends to persist throughout the day. Consequently in excited antagonistic patients we endeavor to terminate treatment when the patient is quiet, drowsy and affable. In cases in which there are severe delusional ideas we terminate as a rule after coma has been established. If the patient is stuporous or slowed down we terminate during a period of increased activity.

It is necessary to stress that the psychotherapeutic aspect of the treatment is important. In this treatment, however, psychotherapy is based on a somewhat different principle from that which obtains in other therapy. The usual concept underlying psychotherapy is that there is a conflict between desires or fears and that this conflict is causal of the abnormal behavior. Under such circumstances it is the object of psychotherapy to find a solution by compromise or by removal of one of the conflicting trends. In insulin treatment this appears to be quite unnecessary. Indeed, the direction of the patient's attention to his psychotic behavior and a deep probing into painful experiences that are attendant on such psychotherapeutic procedures are definitely contraindicated. We abandoned this early in favor of dealing with the patient in such a way that he was kept as tranquil as possible both during the treatment and during the treatment-free periods. It is particularly important that during treatment all stimuli should be reduced as far as possible and to this end the room is kept somewhat darkened and kept as free from sound as possible.

DANGERS

As can be readily grasped from the nature of the treatment, great care and vigilance are required throughout the period of treatment. The outstanding dangers are the possibility of delayed relapse into hyperinsulinism and failure to recognize it. When vomiting occurs or when the patient eats inadequately or even when he has eaten a good—but under the circumstances, inadequate—meal, the symptoms of hyperinsulinism may come on later in the day. In two cases we have seen these symptoms reappear as late as seven hours after the termination of treatment. Should these symptoms not be noticed and should the patient pass

¹¹ Wohlwill F. Ueber Hirnbefunde bei Insulinüberdosierung. *Klin. Wochenschr.* 7: 344 (Feb. 19) 1928. Stief A. and Tokay L. Beiträge zur Histopathologie der experimentellen Insulinvergiftung. *Ztschr. f. d. ges. Neurol. u. Psychiat.* 139: 424 1932.

during his sleep into progressively more severe degrees of hypoglycemia, the results may be extremely unfavorable

A second danger consists of collapse during a convulsive seizure. We have seen perhaps thirty or thirty-five seizures in all but have noted no very serious degrees of collapse beyond stoppage of respiration for periods of up to twenty seconds and some passing instability of the pulse. We consider that when convulsions occur treatment should be terminated immediately by means of intravenous sugar. In view of the observations of Cannon, McIver and Bliss¹² that in experimental animals larger doses of insulin evoke secondary discharge of epinephrine from the adrenal glands, we made a special search for possible epinephrine symptoms when seizures were threatening. At such times it was noted that the pulse became more frequent, that there was some diminution in sweating and that the pupils widened. This widening usually appeared immediately before the bursts of clonic shocks which precede, as a rule, the full-blown seizure. During this preconvulsive period the patient's general attitude is one of defense and, though he is usually very clouded, one gets a general impression of apprehension. Shaking the patient or moving him briskly, as in preparing him for an intravenous injection, intensifies the clonic shocks and, on one or two occasions, particularly active interference such as turning him quickly in bed has been followed by a seizure. At these times, too, there is often a marked degree of exophthalmos, this symptom also increasing on interference. On the other hand, we have failed to produce seizures by means of intravenous injection of epinephrine ($\frac{1}{200,000}$ mg.)

A third danger is that of aspiration pneumonia. During treatment there is usually increased salivation and the saliva is particularly sticky. Should the swallowing reflex be abolished in the latter stages of coma, there is a danger that the saliva may make its way down into the lungs. This can be overcome by having the patient lying in a semiprone position whereby the mouth is lower than the gullet.

A fourth possible danger is that of complications arising from the low body temperatures that are sometimes produced. Although we have recorded rectal temperatures as low as 92° F., we have not seen any ill effects from this cause.

There are a number of other contingencies that arise rather infrequently but should be mentioned. Occasionally one sees a hemiplegia or a more localized paresis which, however, passes away within the course of a few hours. It is our impression that the disappearance is hastened by giving large amounts of sugar. We have noted on two occasions that the final disappearance immediately followed the administration of dextrose. Cases have been reported in the literature in which the paresis has persisted for a few days (Ravid,¹³ Miller and Trescher¹⁴). Spasm of the glottis has been noticed by us on one or two occasions and pulmonary edema has been recorded, although we have not seen it in our series. These symptoms are rapidly abolished by means of intravenous dextrose.

A number of fatalities have been reported, particularly in the earlier literature.¹⁴ The mortality rate amounts to rather less than 1 per cent, which, bearing

in mind the severity of the disorder and the extremely poor outlook, is not a great number if it at all exceeds the normal expectancy for the time period involved. These fatalities on postmortem examination have shown in one case extensive brain changes, these being associated with an unrecognized return of the hypoglycemia, the patient having remained for about forty-six hours in a comatose condition before death. In another case very severe convulsions developed immediately following treatment. There were abnormal symptoms and the patient went downhill rapidly and died. Post mortem she was found to have an acute pancreatitis. A third patient collapsed a short while after termination of treatment and post mortem was found to have a coronary stenosis. As will be seen from the previous description of the technic, alterations have latterly been made which render it unlikely that fatalities from these causes, with the exception of the rather strange case of pancreatitis, would happen again.

RESULTS

Treatment has been completed in seventeen cases. These patients were treated from five to six times a week over periods that ranged from two to ten months. Of our group two have apparently recovered and five others have shown themselves capable of being at home for varying periods. Of the remaining cases five showed no improvement. No ill effects were noted even in cases in which treatment had been prolonged. When improvement does occur, the first changes consist in an increased interest in the environment. Later there are changes in the formal behavior. The patient who was formerly overactive and impulsive becomes increasingly quieter and more orderly. Underactive patients who have been refusing to eat or speak now become increasingly aware of their surroundings, start to talk more freely and begin to feed themselves. Patients who have been suffering from severe hallucinations and delusions find these gradually subsiding. They mean less and less to the patient and, in favorable cases, finally disappear. The capacity to concentrate comes back. In some cases there are interesting changes in the sex life of the individual. Patients who showed no apparent sex interest or only perverted sex interests begin to reveal more and more of a healthy heterosexual trend. This recovery is, however, quite slow, and it may take weeks or months before the best results can be obtained.

Relapses are frequent. Sometimes it is possible to ascribe the relapse to errors in the technic and sometimes they appear to be due to psychologic factors as, for instance, when some one endeavors to probe into the causes of the patient's earlier breakdown while his recovery is still in its early stages.

CONCLUSION

Our year's experience leads us to feel that the Sakel method is a promising therapeutic approach to the schizophrenic problem. In our hands the method has not yet yielded the high percentage of recoveries claimed from some European centers, but since that experience appears to be a considerable factor, we believe it is wise to suspend judgment as to the final efficacy of the method. In view of the well known tendency of the schizophrenia reaction to show considerable fluctuation both in its form and in its intensity, we feel that considerable care must be exercised to distinguish between the results of treatment and the endogenous fluctuations.

Apart from the value of insulin treatment in the immediate alleviation of early cases there are many

questions such as the permanence of the recoveries, the question of the most favorable kind of case and the light which this method may throw on etiology, which can be answered only after further investigation. We would emphasize most strongly that since experience plays such a large role in determining efficacy and forestalling danger, the method should not be attempted save in an adequately equipped mental hospital or under the immediate supervision of a well trained psychiatrist, who should also be capable of meeting the emergencies that may arise.

THE HYPOGLYCEMIC TREATMENT OF SCHIZOPHRENIA

A PRELIMINARY REPORT, WITH PARTICULAR REFERENCE TO THE QUALITATIVE STUDY OF REMISSIONS

CHARLES A. RYMER, M.D.
JOHN D. BENJAMIN, M.D.
AND
FRANKLIN G. EBAUGH, M.D.
DENVER

In presenting a preliminary report of our experiences with the hypoglycemic treatment of the schizophrenic reactions, we wish to discuss briefly the methods of study employed as well as the actual results obtained in our small series of completed cases. Most of the writers in this field have recognized the great difficulty involved in the evaluation of therapeutic results, arising chiefly from the heterogeneity of the schizophrenic psychoses, from the conflicting statistics regarding the "natural" prognosis of these conditions, taken as a group, and from the lack of reliable prognostic criteria in the individual cases. If these factors, even in a large series, militate considerably against the validity of any purely statistical comparison between treated and untreated cases, it is apparent that in a small series such as ours a statistical evaluation would be worthless. We do not intend to imply that the value of Sakel's method cannot be demonstrated by a quantitative approach, on the contrary, we feel that the publications of Dussik and Sakel¹ and of Mueller² present convincing evidence that insulin shock is a valuable therapeutic weapon in the treatment of schizophrenia, and our own results to date, as well as those of most other investigators, confirm this. In order to arrive at a qualitative judgment regarding the efficacy of and indications for the treatment, however, as well as to utilize it to the utmost in furthering our very inadequate knowledge of the schizophrenic reactions, we feel that more precise methods of study are essential, such methods must of necessity be based not only on the observations in cases treated with hypoglycemia, but also on more exact studies of the schizophrenic reactions in general, especially from the point of view of differentiation, clinical course and prognosis. One of us has been engaged for the past two years in a series of investigations designed to clarify some of these problems, since it was felt that without such clarification both etiologic and therapeutic research were greatly handicapped. This is not the place to report in any

detail the results of these studies, which will be presented elsewhere on their completion, here we would merely touch on a few of them as they relate to our work with insulin shock treatment.

In evaluating the therapeutic efficacy of any treatment of schizophrenia the following factors must be considered:

- 1 The percentage of remissions and social recoveries
- 2 The duration of the remissions
- 3 The quality of the remissions
- 4 The speed of recovery

Up to the present time we have completed treatment of seven patients, of whom six had been manifestly ill for periods varying from ten days to three months, whereas one patient had chronic paranoid schizophrenia of at least five years' duration. The diagnoses, duration of illness, and therapeutic results are shown in table 1.

In reviewing the results, one feature of interest is immediately apparent. In five of the seven cases, including the one chronic case, excellent results were obtained, in the two other cases, both of recent onset, no noteworthy changes occurred, and both of these cases were characterized by marked affective components. This appears particularly significant in view of the well known tendency of such cases to spontaneous remissions. If, as some writers have asserted, the effect of hypoglycemia were merely to further, by means of nonspecific shock, a natural tendency to recovery, one would expect these cases to react at least as well as the paranoid. Among seven additional patients whom we now have under treatment we again included two with pronounced affective components and again have observed a lack of therapeutic response. The condition in both of the cases in our present series remained unchanged for a period of several weeks after termi-

TABLE 1—Diagnoses, Duration and Therapeutic Results

Case	Age	Sex	Clinical Diagnosis	Duration of Illness Before Treatment	Clinical Result
1	26	♀	Catatonic schizophrenia (stupor) with underlying paranoid trends	Two and one half months	Remission
2	44	♀	Paranoid schizophrenia	Five years	Greatly improved (social recovery)
3	32	♀	Catatonic schizophrenia with marked depression	Two months	No change
4	23	♂	Paranoid schizophrenia	Two months	Remission
5	27	♂	Paranoid schizophrenia	Three months	Greatly improved (social recovery)
6	26	♀	Paranoid schizophrenia with manic features	One month	No change
7	32	♂	Paranoid schizophrenia	Ten days	Greatly improved (social recovery)

nation of the insulin treatment and then began to show some improvement, at the present time both patients are well on the way to good social recovery.

In distinguishing between complete remissions and social recoveries or marked improvements we have, for statistical purposes, followed the example of Sakel and Mueller. It is clear, however, that these designations are open to considerable variation in usage. Sakel³ has defined a full remission as one in which "the patient is not only symptom free but has full insight into his illness, normal emotional reactions, and can return to his former work." He

speaks of a "good" remission as one "in which the patient is free of schizophrenic symptoms, and can resume his former work but has some slight degree of defect" The diagnosis of "some slight degree of defect" will in many cases depend on one's concept of schizophrenic symptomatology, as will the finding that the emotional reactions are normal We are in full accord with Bleuler's statement that "in every case the diagnosis of recovery is dependent upon the psychological skill of the examiner, and above all on the amount of time which the psychiatrist has at his disposal for the observation and examination of the patient One cannot directly diagnose complete recovery, one assumes it when careful searching reveals no signs of the illness He who has little time to examine his patients will find many recoveries which another would regard as improvements

A return to the condition existing before an acute episode is not at all rare, but this cannot be considered recovery if an insidious schizophrenia had already markedly changed the personality of the patient before the acute episode" We have designated as remissions those cases in which a careful clinical examination failed to reveal any evidence of schizophrenia and in which the opinion of relatives and friends concurred with that of the medical staff that the patient was apparently restored to com-

such but rather with those lasting over a considerable period of time Thus Mayer-Gross⁴ found that of 294 patients with schizophrenia admitted to the Heidelberg clinic in 1912 and 1913 eighty-nine, or 30 per cent, had maintained good social recoveries from sixteen to seven years later, and Otto-Martensen and E Meyer have published comparable results The statistics regarding remissions irrespective of duration vary from 20 to 35 per cent for all cases up to more than 50 per cent for acute cases, but none of them give sufficient information concerning the type of cases examined to be of any real statistical value The number of variables in the schizophrenic reactions is so great that for purposes of exact comparison it is advisable to subdivide both treated and untreated cases according to all the available prognostic criteria, such as age, body habitus, heredity, prepsychotic personality and clinical course, including type of onset" In studies over the past two years one of us has found that the presence and degree of formal thinking disorders is of particular importance in this respect A study taking all these factors into account is now in progress in our hospital and can eventually be used as a control for the insulin series In the meantime, however, we are in full accord with Mueller that incomplete statistical studies are of little value At all events, if Sakel's and Mueller's percent

TABLE 2—Course of Treatment

Case	Diagnosis	Result of Treatment	Time Elapsed Since Termination of Treatment	Length of Treatment (in Treatment Days)	Length of Phase I Days	Shock Dosage Units	Number of Shocks	Wet Shocks	Dry Shocks	Consultations	Myoclonic Twitchings, Days
1	Catatonic stupor	Very good	6 months	4 ⁰	10	70-85	29	29	0	0	0
2	Paranoid	Good	4½ months	68	10	85	54	54	0	1	(6) mild
3	Catatonic with depression	Poor	3½ months	41	12	110	6	2	4	0	(8) mild
4	Paranoid	Very good	3 months	60	13	185-200	43	43	0	1	(6) severe
5	Paranoid	Good	3 months	74	11	180	60	53	7	2	(3½) severe
6	Paranoid with manic features	Poor	1½ months	72	18	180-190	40	32	18	1	(3) mild
7	Paranoid	Good	2 months	70	13	200	33	33	0	2	(4) severe

plete health, although, as will be seen later, in every case finer methods of examination revealed some schizophrenic features By marked improvement with social recovery we mean that all gross schizophrenic symptoms (delusions, hallucinations, odd behavior, catatonic symptoms, dissociation of affect, and so on) have entirely disappeared and that the patient is able to return to work, but that some slight defects can be elicited by careful clinical examination, although to the eyes of the relatives the patients are entirely normal In both of these types of improvement, insight into the pathologic nature of the previous symptoms was present We have not yet encountered a third type of "recovery," seen so frequently in ordinary clinical practice, in which gross symptoms still persist in a much milder form and insight is lacking, but the patients nevertheless are capable of a return to work with fair social adjustment We prefer the term "improvement" to "social recovery" for these cases

Although these considerations are essential to the qualitative study of remissions, to which we shall return later, they are of only slight practical importance in the quantitative evaluation of the results of hypoglycemia since the available statistics on spontaneous remissions do not attempt to distinguish between various degrees of recovery but use only the criteria of social adjustment and the absence of obvious schizophrenic symptoms Unfortunately, however, there are no studies which are entirely satisfactory for comparison with a large insulin series Most of the statistics, in fact, do not deal with the number of spontaneous remissions as

ages of remissions are confirmed by other workers using the same technic, there will be no doubt as to the quantitative efficacy of the method

As regards the very important question of the duration of the remissions, no definite knowledge will of course be available for some years Nevertheless the fact that the follow-up studies of Dussik and Sakel show so few recurrences and that Mueller has seen none to date is in marked contrast to the ordinary clinical experience in an equal number of spontaneous remissions Not one of our cases has shown any tendency to relapse, on the contrary, most of them appear to be consolidating their gains Patient 5, for example, showed a mild degree of seclusiveness when first discharged from the hospital, but now, three months later, this trait has practically disappeared In this connection the remarks of Bowman⁶ and Wortis⁷ to the effect that it is unfair to judge Sakel's method on the basis of results reported by authors not using his strict technic are especially pertinent Wortis,⁸ in his excellent review of the history and present status of the treatment, cites the work at Wilna in which the patients were given much less intensive treatment and in which a large number of remissions were unsustained While there

is of course no direct proof that a causal relationship between these two facts exists, it is certainly justifiable to assume it until an equal number of unsustained remissions are reported by investigators using Sakel's technic

One factor that has been given little mention to date is the speed of recovery. In any comparison between insulin and spontaneous remissions it must be remembered that the latter often occur only after many months of hospitalization. Not only is this earlier recovery worth much to the patient and his family, but its existence is a telling argument against the hypercritical and unjustified assumption that "most" insulin remissions are in reality spontaneous.

The most promising approach at the present time appears to us to lie in the qualitative study of remissions. We wish to know not only whether the insulin treatment increases the number of remissions but also whether these are in any way better than or different from spontaneous remissions. Sakel, Mueller and Wortis have already expressed the opinion that, taken as a whole, the insulin remissions impress them as being of better quality. Mueller in particular has called attention to the unusual degree of emotional rapport seen in the patients following recovery, and our own impression is that insight, rapport and general stability are on a higher level than is usually found in untreated but recovered patients. Such an opinion is, however, highly subjective. We are attempting to study objectively the quality of the remissions by two methods which we have utilized on a large scale in investigations of the schizophrenic psychoses: the Rorschach test and a special mental status⁹ designed to elicit certain types of schizophrenic thinking disorders. Without wishing in this place to enter into a discussion either of the highly complex and debatable problem of thinking disorders in schizophrenia or of the applicability and validity of the Rorschach test,¹⁰ we would state that the results to date indicate that the better insulin remissions show a degree of improvement which, in our experience, is not found in even the best spontaneous recoveries. We should add that the Rorschach test reveals some degree of schizophrenic defect in all "recovered" cases, both insulin and untreated, except in certain schizophrenic-like (schizoid) reactions in which the typical Rorschach manifestations are absent from the beginning.

A detailed discussion of the problems of technic and of laboratory investigations being undertaken must be reserved for a subsequent communication based on a larger number of treated cases. Technically we are attempting to follow Sakel's recommendations exactly, although it should be mentioned that in case 1, a catatonic stupor, deep shocks were used before we were acquainted with Sakel's modification of treatment for these cases. Table 2 summarizes a few pertinent facts concerning the course of the treatment in the seven cases.

As the table shows, neither myoclonic twitches nor convulsions interfere with a good therapeutic result. On the other hand, both of the unsatisfactory cases showed a comparatively large number of dry shocks as compared with wet shocks. The women as a group required a much smaller dosage of insulin than did the men. In the male and female groups respectively the excellence of the therapeutic effect appeared to some extent to be in inverse proportion to the size of the shock dosage, a factor which also found expression in the length of the induction period.

CONCLUSION

We feel that the results of the hypoglycemic treatment of schizophrenia to date are highly encouraging, although a long period of time will be necessary before a definite opinion can be given. Apart from its therapeutic value, the method offers an unusual opportunity for clinical and laboratory research.

4200 East Ninth Avenue

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs CAMERON AND HOSKINS AND
DRs RYMER, BENJAMIN AND EBAUGH

DR RICHARD H. YOUNG, Omaha. The papers on hypoglycemia today express the need for further accumulation of data with the original method and a special type of information obtainable by what has been termed a qualitative method, before reorientation takes place. It would seem too early to assume that a response to this treatment affords evidence of an organic etiology. About all that can be said is that the treatment brings about a change in certain cases because of an effect that is exerted chiefly at the physiologic level of integration. It is to be noted that the changes do not seem to reflect themselves in our studies of the blood mineral pattern taken under basal conditions (before insulin) at different times during the course of treatment. With regard to physiologic changes the same variations have been seen in insulin sensitivity, which may be of some prognostic importance. The insulin tolerance tests before treatment have given little information. Of interest is that four of forty-five patients complained of marked weakness after two or three weeks of treatment and asked for additional rest days. It was found that their blood pressures, which had formerly been normal and showed the usual elevation during hypoglycemia, were between 85 and 100 systolic. The serum potassiums were high normals and the chlorides usually in the lower range of normal. In two cases the nonprotein nitrogen was increased moderately. No studies of mineral balance or potassium tolerance tests were made. This reaction was associated also with a depressive affect in all four cases and a lack of improvement under treatment. This leads to the remarks concerning affect in the paper of Drs Rymer, Benjamin and Ebaugh. I should like to know what kind of affective reactions in their cases were associated with poor results. In our series it was particularly cases with depressive features that did poorly. Our experience is in line with other statements in these reports, and at the expense of being trite I shall conclude by (1) emphasizing the dangers, (2) urging a utilization of the opportunities for other types of treatment that the therapy presents in the form of lucid periods, and (3) commending the type of study that is being carried out.

DR LLOYD H. ZIEGLER, Albany, N. Y. The only intelligent approach to the problem is research aiming at prevention or cure. By fortuitous circumstance, as the results of research may be, Dr Sakel has brought a large ray of hope for multitudes of such patients. One should not cease hoping that, as in the case of smallpox, a prevention may be discovered that will obviate the necessity for cure. For a long time it has been known that simple infections, such as a furuncle, might cause a schizophrenic patient to abandon his seclusion and self-limited world of phantasy and seek relief from the infection. On the other hand infected colons and infected teeth have been removed because of their supposed effect on the patient. A successful merchant of my acquaintance, not schizophrenic, was changed from a sour, antagonistic, selfish person to a pleasant, friendly, tolerant one after a severe attack of pneumonia during which he was very delirious. One schizophrenic patient was markedly changed for the better by alcohol. The Russians have reported similar experiences. Carbon dioxide and sodium amytal have produced marvelous transitory effects. The induction of a prolonged period of sleep (several weeks) has had a certain amount of promise. Spontaneous changes apparently occur to produce a variable remission rate. It behooves us to inquire further into the factors that may be related to this so-called spontaneity. Drs Rymer, Benjamin and Ebaugh have gotten nicely started in this problem and have presented splendid criteria for the evaluation of therapy, together with the early results in a small

⁹ To be published later.

¹⁰ Benjamin J. D. and Ebaugh F. G. The Diagnostic Validity of the Rorschach Test. *Am. J. Psychiat.* to be published.

group Drs Cameron and Hoskins have made a clear statement of technique, have shown the dangers to be guarded against, and have reported the results so far attained with patients having more chronic disorders. In scanning the horizon of treatment one cannot but be impressed with the fact that there has been some order in the steps that have led to the adoption of insulin therapy. Insulin enables one to subject the patient to an internal hunger or deprivation, leading to unconsciousness and coma. If the usual patterns of behavior are not too habitual or rigid, the recovery from coma may be the point of departure for other behavior more in keeping with social demands. Or the brain cells themselves may have been conditioned to provide untapped resources dormant in the biogenetic anomaly known as schizophrenia. In either sense the patient is "born again," not so unlike the concepts held by our friends the spiritual advisers. In the one instance it is produced by biochemical means, in the other by a profound emotional shake up. One may make the deduction that insulin may be only one of several drugs or methods that may accomplish similar results. Some of these are beginning to appear now (metrazol).

DR FRANK N. ALLAN, Boston. The encouraging results of treatment of schizophrenia now under discussion will lead to public demand for insulin therapy, and physicians will be asked to treat all types of mental disorder under all sorts of conditions. I cannot pass judgment on the merits of the treatment through personal experience. I have been concerned with the use of insulin in conditions in which it is desired to avoid hypoglycemic reactions, so that I am unable to discuss the benefit of this treatment in which insulin shock is deliberately induced. My observation arouses the fear that whatever merit the treatment possesses may be lost unless it is judiciously employed. The fact that irreversible harmful effects on the nervous system are possible, as shown by Moersch and Kernohan, and the fact that during treatment the patient may come close to loss of life make skilled medical attention imperative. Evaluation of results demands expert psychiatric study before and after. Prolonged repetition of treatment appears necessary. It is not a matter for casual treatment in general hospitals, and certainly not in office or home. I would therefore strongly support the plea to internists and general practitioners to refrain from undertaking the treatment. Any patient suffering from a mental disorder serious enough to warrant consideration of insulin shock should be admitted to a hospital and have expert psychiatric care. Let us leave the matter entirely in the hands of psychiatrists who have had experience with the treatment or who can develop experience under conditions most favorable to the patient. Any other policy may seriously retard progress.

DR THEODORE R. ROBIE, East Orange, N. J. All I have to report is a rather general survey of seven cases treated so far. In two of the seven, treatment has been completed, with recovery. The first patient had acute catatonia of extreme type and has been at home now for six months, completely recovered and back at school. The second patient, with hebephrenia of three months' duration, now back at home, is quite normal. The other three patients with dementia praecox are still under treatment and it is unfair to report on them, but one in less than three weeks has shown a very remarkable recovery, and that is a case of some four years' duration, considered more or less hopeless before treatment was started. To make the seven cases complete, of the remaining two the first was a cross between an acute maniacal state and catatonic excitement. In less than ten days this man was brought into a normal mental state. He went home from the sanatorium in less than three weeks after being placed on treatment and is in excellent health. The other patient who had a manic-depressive psychosis with markedly depressive trends and who developed fugue states, has been treated has been home two months, and is clear of recurrent fugue states, which had been recurring previously about every two weeks. There are two points I would like to mention about bringing the patients out of coma. I have felt that it was better to use the intravenous dextrose method for patients who go into deep coma first because of the factor of psychic shock, which occurs when the nasal tube is used, I tried the nasal tube method and in each case got such a tremendous reaction that I did not feel it was desirable, second, the rapidity with which one can bring the patient out of coma and know just exactly where one stands.

DR JULIUS STEINFELD, Peoria, Ill. In the past ten months at the Michell Institute I have administered the insulin shock treatment, with the help of Dr. Burton, in twenty-five cases, including nineteen of schizophrenia, four of dipsomania and two of depression. The number of remissions compares with those pointed out by other authors. I shall discuss two observations. First, the value of epileptic seizures. I have seen a few patients in whom the improvement with insulin therapy reached a fixed level, and further improvement followed the use of metrazol. The method was similar to the methods used by other workers. The patient was given insulin early in the morning and later, when he showed signs of hypoglycemia, was given metrazol intravenously, which was followed immediately by a seizure. The seizures following the combined use of insulin and metrazol are greater and more prolonged than those produced by metrazol alone. This was noted especially in two patients who had been ill for more than four years. Second, the problem of gaining new insight into the schizophrenic process, particularly regarding the question of whether the disease leans more toward the organic or the functional side. An answer to this question would determine whether psychotherapy is indicated. In a paper presented recently before the Psycho-Analytic Society in Chicago I tried to show the following. During insulin therapy, regressive tendencies as expressed by mental and physical reactions are clearly visible. The lowest possible level of regression reached is exemplified by the assumption of childlike attitudes and such symptoms as sucking movements with the lips and tongue and infantile reflexes. The mental reactions of the regressed patient are well demonstrated in one instance by the following remarks: "I don't want to become any better. I should like to remain in this stage wherein I feel like a little child. Please don't give me more of those treatments, it disturbs my whole life." There is no doubt that from the standpoint of the deeply regressed patient the shock treatment disturbs the present view of life. In those cases I think one has to approach the patient in the way of psychotherapy and help him in finding a new attitude to a new world.

DR KARL THEO. DUSSIK, Vienna. Considering that more than 70 per cent of all patients in hospitals for mental diseases have dementia praecox, the insulin shock treatment as worked out by Dr. Manfred Sakel of Vienna may be regarded as the greatest advance in psychiatric therapy since the malaria treatment of dementia paralytica, discovered by Wagner-Jauregg, the former head of our clinic in Vienna. Prof. Otto Poetzl, the successor of Wagner-Jauregg, was courageous enough to try and to recommend the insulin shock treatment, although it seemed at first dangerous. After four years of using this treatment in a special department of our clinic the facts observed have convinced us that this method surpasses by far all the other methods thus far discovered to treat schizophrenic subjects. As I worked from the first day in using this method in our clinic I can confirm its real effect. The personality of the patient can often be changed so entirely during the hypoglycemic reactions that it seems as though the hypoglycemic treatment has created a new being. A recent examination of the first ten paranoid cases with a bad prognosis treated in my department of the clinic of Professor Poetzl for more than three years showed that eight patients of ten are today quite well and able to work in their respective professions as physician, engineer, bookkeeper and so on. It also demonstrated that the therapeutic effect in most cases has a good prognosis for the future. The treatment is generally not dangerous, provided the method is employed carefully, the doctor has had sufficient experience, and the patient does not have another organic illness, especially of the heart. It is, however, necessary that the treatment be begun as early as possible after the onset of the illness, because the percentage of successes, the quality of remission and the safety against relapse are much better the earlier the treatment is instituted. Sakel's method is the result of many years of seeking out of working. It is possible to combine with other, particularly endocrine and vegetative drugs such as epinephrine, adrenal cortex extract, pituitary and thyroid extracts or ergotamine and vitamins, but I think we should try first the method of hypoglycemia alone and be very cautious with the other drugs. We think that in addition to the therapeutic effects it will be possible to find answers to many ques-

tions regarding the psychotherapy of psychosis. We are hoping, too, for a further advance in experimental psychopathology. We think it will be possible to separate groups of schizophrenic patients and thus get more information about the etiology and the pictures and symptoms of psychosis. We believe that today psychiatrists of the whole world are cooperating more than ever before. A few days ago Dr Sakel spoke before the Psychiatric Congress in Bern, which was occupied almost entirely with this treatment. Dr Sakel was grateful for the sympathetic reception that this work received in the United States.

DR S. T. GORDY, Philadelphia. I should like to ask whether there has been any differentiation made between the types of schizophrenia—that is, the catatonic, heterophrenic, paranoid and simple types—and whether they offer any difference in their prognostic outlook under this method.

DR H. E. HINWICH, Albany, N. Y. I should like to call attention to another aspect of this problem, namely, why is it that insulin helps brain conditions? Why does it single out the brain or central nervous system from among all the other organs of the body? In an effort to answer such a question I drew venous blood from muscle and from brain when insulin was given in large doses to dogs. It was found that, no matter how low the blood sugar became, the blood coming back from the muscle was usually dark venous blood. On the contrary, the blood coming back from the brain became lighter in color and finally came back quite arterialized when the blood sugar was low. Apparently the brain, under hypoglycemia, ceases to maintain its normal oxygen consumption. This phenomenon may be explained if it is recalled that muscle may oxidize both fat and carbohydrate. When carbohydrate becomes less available, muscle will oxidize increasing amounts of fat. On the other hand the evidence to date seems to indicate that the brain can oxidize only one foodstuff, carbohydrate, and that when carbohydrate is removed, as the result of the low blood sugar, the brain is temporarily deprived of its energy requirements. Thus we have an answer to the question why insulin produces such a result because the brain chiefly requires carbohydrate, and insulin deprives the brain of this foodstuff. On the other hand, the question of just where this observation fits into the amelioration of the condition of schizophrenia is still to be solved.

DR WALTER FREEMAN, Washington, D. C. In my chairman's address six years ago, I drew on my imagination with regard to the psychoses and spoke about the chemistry of the psychoses under the title "psychochemistry." I suggested that some process might be found underlying the psychoses that would render their treatment as easy as that of some of the deficiency diseases, and I mentioned rickets as an example. I do not say that the treatment as here outlined is as successful as the treatment of rickets or of any other deficiency disease, or that the cured percentage is as high, but on the other hand I do not think that the ultimate in therapeutic possibilities has been reached. As Dr Steinfeld mentioned the possibilities of therapy may be improved by producing convulsions. I heartily second that statement, although it is based on a very small series of cases.

DR J. M. NIELSEN, Los Angeles. It seemed to me striking that the authors have said but little about the physical manifestations of dementia praecox yet they are always present. It is evident that dementia praecox affects not merely the brain but the entire body. Before the insulin treatment was discovered, fairly good results were obtained with sodium ricinoleate or with old fashioned castor oil. In the acute schizophrenic reaction one could get a 50 per cent recovery with those methods and a great deal of physical improvement was seen. With insulin exactly the same changes take place. The muddiness, dull skin clears up, the subcutaneous tissue clears and patients gain in weight. Before the insulin treatment the skin is thick, and it thins out and becomes relatively normal skin, the hair is matted but clears up and becomes of a fine texture, healthier looking throughout, the hands warm up and there is a general improvement in the entire physical being and not only in the mental state. It seems to me that there is a parallelism between the general physical state and the mental improvement.

DR R. G. HOSKINS, Boston. In considering therapeutic results, attention should be paid to the base line from which one is operating. Neither insulin nor anything else can be expected to restore the patient to better than his prepsychotic condition. Special interest attaches to insulin as a research tool. Attention has been focused on the patient who responds favorably to insulin therapy. Perhaps more important at the present time is the patient who does not respond. If we can learn from penetrating research why some patients do not respond we may learn the nature of schizophrenia itself. Abnormal oxygen metabolism seems to be a central feature in the psychosis. Hence the insulin treatment should be studied in relation to that factor. I was correspondingly glad to learn of Dr Hinwisch's illuminating new work on this subject. It is important to recognize that the curative effect of insulin may be exerted not in the brain itself but in the regulatory mechanisms whereby the oxygen metabolism is regulated. These may be endocrine, vitamin or what-not. Dr Freeman has suggested that organic iron may be an important factor. If schizophrenia originates in brain disorder and if disturbed oxygen metabolism is a central feature, we shall have to think of the oxidative enzymes. The oxidation of dextrose to carbon dioxide and water involves a series of chain reactions each of which is regulated by its own rather complex enzyme system. The pathology may consist in abnormality of these enzymes. This possibility may explain why the morphologic pathologist has sought in vain for a basis of the disorder. I am in disagreement with Dr Allan in his belief that the general practitioner has no duty at this time in the insulin treatment of schizophrenia. I feel that the man without special facilities may have the most important part to play. It seems to be the consensus of all who have studied the subject that the hope of insulin treatment is greatest in the most recent cases and that as time passes hope wanes. To the extent to which this is true, the responsibility comes back to the general practitioner to get the patients to the psychiatrist who is going to administer the treatment at the earliest possible date.

DR D. EWEN CAMERON, Worcester, Mass. I should like to comment on Dr Ziegler's statement that he feels that further research is necessary. That to my mind, is the paramount issue before us at the present time. The insulin treatment is something like an iceberg—what is before our eyes is very much less than what we do not grasp. Perhaps it is an evidence of good teamwork that what I had in mind to emphasize further in conclusion has already been taken up by my co-author, Dr Hoskins. I should like to drive the nail a little farther and say that I have had occasion, during the last year, to be present at a great many discussions on the insulin treatment, at which a great deal of emphasis was placed on the dramatic results, results which have occurred in patients who have been sick perhaps a long time, results that have occurred almost overnight. At the same time I think we should keep an eye on patients who do not recover. As the authors have pointed out, we may get some very interesting answers from their study. The other nail that I want to push a bit farther is the necessity of getting earlier cases. I feel that we are rapidly approaching the time when we may hope to launch a schizophrenia campaign comparable to the tuberculosis or cancer campaigns. It may not be primarily or exclusively on the basis of the insulin treatment, although it does seem at present that the insulin treatment might have first place. I feel that the early symptoms of schizophrenia are a legitimate source of study, to provide us with material to hand over to the lay worker, to the relatives and to the nonpsychiatric physicians so that they may earlier recognize the cases. Our research should likewise be directed toward finding what the laboratories can tell us regarding the changes that come in the very early stages. It may be that from the psychologic and biochemical laboratories we shall be able in the not too distant future to evolve a test comparable in efficacy to x-ray examination in the case of early tuberculosis. I dare not yet suggest anything having the specificity of the Wassermann test in syphilis.

DR CHARLES A. RIVIER, Denver. In response to Dr Young's question, the two cases with affective components comprised a catatonia with marked depression and a paranoid schizophrenia with manic features. We are certainly in agreement that every avenue of approach must be kept open in studying this method.

PROPHYLACTIC VACCINATION AGAINST
INTRACRANIAL COMPLICATIONSFOLLOWING PNEUMOCOCCUS TYPE III
MASTOIDITISJOSEPH L. GOLDMAN, M.D.
AND
CECELE HERSCHBERGER, B.S.
NEW YORK

It is well known that the presence of the type III pneumococcus in acute mastoiditis offers a serious prognosis because of the frequency with which subsequent intracranial complications develop. Meningitis is the complication usually encountered. As there is an interval of from one to several weeks, as a rule, between the initial infection and the time when complications occur, attempts to induce a state of active acquired immunity should receive consideration.

A number of workers in recent years have been able to protect animals against pneumococcal infections in a short period by vaccination. The following are some of the significant and pertinent reports on the subject.

Barach¹ in 1928 showed that mice can be actively immunized in three days by a single intraperitoneal injection of types I and II pneumococcus vaccine. In his experiments, type-specific antibodies appeared on the third day, increased progressively until the fifth day and remained approximately unchanged until the seventh day. On the third day the mice immunized with type I vaccine resisted 100,000 minimum lethal doses and mice immunized with type II vaccine resisted 10,000 minimum lethal doses. In 1931 Barach² demonstrated the appearance of specific protective substances in human serums four or five days after intravenous and intradermal injections of pneumococcus vaccine. In cases of lobar pneumonia it was possible to evoke type-specific antibodies by the injection of heterologous types of pneumococcus vaccine.

In 1927 Tillett³ was successful in actively immunizing rabbits with type III vaccine against infections with homologous organisms although specific antibodies were not demonstrable. He was able to protect completely 50 per cent of his rabbits and partially an additional 33 per cent by using in his experiments an organism made highly pathogenic by rapid animal passage. The method employed in conferring immunity in this instance consisted of administering injections every other week for six weeks.

Especially significant is the fact that Tillett showed that immunity can be obtained in animals to type III pneumococcus infections in the absence of specific antibodies in the blood serum. In other words, the degree of protection conferred cannot be determined by the presence or amount of agglutinins or precipitins in the serum. Similar observations with the type III pneumo-

coccus had been made previously by Hanes⁴ and by Singer and Adler.⁵

Cecil and Steffen⁶ in 1921 and 1923 conferred complete immunity on monkeys against experimentally produced types I and II pneumonia by three subcutaneous injections of homologous vaccines. With type III vaccine, complete immunity was obtained in 50 per cent of the animals. These workers also stated that specific protective bodies were not demonstrated in the monkeys protected by Pneumococcus types II and III vaccines.

In 1928 Goodner⁷ produced in rabbits by intradermal inoculation with the type I pneumococcus a local lesion which gave rise to a sequence of clinical manifestations that offered many analogies to pneumococcal lobar pneumonia. If sufficient antipneumococcus serum was administered twenty-four hours after the onset of the infection, prompt recovery was effected. Goodner further showed that rabbits could be protected from this intradermal infection by a single vaccination administered five days previously. Also, if the rabbits were vaccinated and then received an injection within the period necessary for the development of this immunity, the course of the consequent disease was shortened in proportion to the interval between vaccination and infection.

Working with the type I pneumococcus, Bull and McKee⁸ in 1927 conferred perfect protection on rabbits in ten days by intravenous inoculation with vaccine against infection by the nasal route. Walsh and Cannon⁹ were recently able to duplicate this protection in five days by intranasal vaccination. Their experiments indicate that the immunity is not strictly local but general. Bull and McKee and Walsh and Cannon also demonstrated immunity without evident protective substances in the blood serum.

In September 1931 this study¹⁰ was undertaken under the guidance of Dr. Gregory Schwartzman and with the cooperation of Dr. Isidore Friesner to determine the efficacy of active immunization against intracranial infections in cases of mastoiditis due to infection with the type III pneumococcus. Every patient with this disease admitted since September 1931 to the otologic service of the Mount Sinai Hospital has been given a course of vaccine therapy. The vaccination was begun as soon as the bacteriologic diagnosis was made. It was necessary of course to culture material taken from every infected mastoid bone at operation so that this form of therapy could be employed.

In 1932 Kolmer and Amano¹¹ published experimental evidence which tends to indicate further the beneficial effect of pneumococcus vaccination. They demonstrated that immunization with types I, II and III pneumococcus autogenous vaccines afford protection

against experimental meningitis in rabbits and on the basis of this work suggested prophylactic vaccination. Their results indicated that intracutaneous injections produce a higher degree of immunity than subcutaneous injections. They were successful in protecting 57 per cent of their rabbits by intracutaneous injections. Intravenous injections with type I pneumococci afforded 100 per cent protection. Oral vaccination with type III pneumococci also yielded 100 per cent protection.

It is appropriate to mention at this point that the old and possibly confusing nomenclature "*Streptococcus mucosus*" or "*Pneumococcus mucosus*" is not employed in our laboratories. All the gram-positive cocci in pairs or chains recovered from patients with acute mastoiditis are classified as either *Streptococcus hemolyticus*-beta, nonmucoid or mucoid variant, or *Pneumococcus* type III. The identification of the latter is based on solubility in bile and the results of agglutination and precipitation tests. If the serologic reactions with the original culture are inconclusive, the organisms are injected into the peritoneal cavity of a mouse and on the following day cultures are made from the heart's blood. This procedure is usually sufficient to restore the type-specific agglutinability and bile solubility of the pneumococcus.

TECHNIC

The vaccination technic originally consisted of six intradermal injections administered at the rate of two a week in the following increasing doses: 0.1, 0.2, 0.3, 0.5, 0.8 and 1 cc. For doses larger than 0.2 cc, several simultaneous injections were made. During the past two years four additional subcutaneous injections have been added. The first inoculation was given within forty-eight hours after the operation or, occasionally, before the operation. In the latter instances, the bacteriologic diagnosis was based on cultures of the discharge from the middle ear. To avoid loss of time, a stock vaccine was used for the initial injection. For the remaining injections an autogenous vaccine was employed. The autogenous vaccine was prepared by growing a pure culture of the type III pneumococcus, obtained from the mastoid pus, in 100 cc of 1 per cent dextrose broth for twenty-four hours. The organisms were centrifugated, washed once and then resuspended in 0.85 per cent sodium chloride solution to obtain a concentration of 600,000,000 organisms per cubic centimeter. The bacteria were then killed by heating at 60 C for one-half hour.

Sixty-one patients with acute mastoiditis due to infection with the type III pneumococcus were admitted to the hospital between September 1931 and April 1937. Of these fifty-six received a full course of vaccine. In the remaining five cases, no vaccine or only one or two injections were given because of deaths occurring shortly after operations. The five deaths were caused by facial erysipelas, accompanied by hemolytic streptococcus bacteremia in two instances, by meningitis which was present on admission to the hospital in two and by meningitis resulting from an operative injury in one.

Of the fifty-six patients who had received a full course of vaccine, four died. In one patient, a woman 66 years old, bronchopneumonia developed six weeks after her operation and three weeks after her discharge from the hospital. Her mastoidectomy wound had healed, and she was in good health before the pneumonic infection set in. In another patient, a man 65 years old, the clinical picture of petrositis was complicated by a squamous cell carcinoma of the nasopharynx, which by extension involved the basisphenoid, the apex of the petrous pyramid and the dura. This patient had had a mastoidectomy one year before at another institution. Operation at this admission uncovered an abscess of the petrous pyramid from which the type III pneumococcus was cultured. He finally succumbed to

meningitis, and gram-positive diplococci, which did not grow out on culture mediums, were found in the spinal fluid.

In the other two instances death was caused by meningitis which was directly secondary to the mastoid infection. One patient, a Negro 42 years old, was admitted with a history of aural pain for five weeks, aural discharge for four weeks and hemicranial headache for two weeks. At the operation considerable destruction of the mastoid was observed extending into the solid angle between the horizontal and superior semicircular canals and into the deeper cells between the facial nerve and the sigmoid sinus. The patient convalesced satisfactorily, and during convalescence he received the autogenous vaccine. Six weeks after operation however, he returned with recurrent mastoiditis. This time *Streptococcus hemolyticus* was isolated from the pus. After three months, during which time he complained of headaches, meningitis due to infection with the type III pneumococcus developed. Necropsy was not done. The other patient, a man 39 years old, entered the hospital with severe hemicranial pain for two weeks, profuse aural discharge, sagging of the external auditory canal wall and exquisite mastoid tenderness. The x-ray examination revealed destruction of bone and absorption in the petrous pyramid. At operation a markedly pneumatic and diseased mastoid bone was observed. A large pit, situated at the superior-posterior margin of the petrous pyramid in the region of the superior semicircular canal, was followed into the pyramid, and about one-half drachm (2 cc) of pus was evacuated. A drain was inserted. Although the patient improved after the operation, he was never entirely free from pain in the head. Three weeks after operation, meningitis developed. In this instance also necropsy was not done. We wish to point out that the last two patients presented indications of infection of the petrous pyramid.

The remaining fifty-two patients who received full courses of vaccine made uneventful recoveries. Dr. Friesner, the chief of the service, has expressed the belief that these vaccinated patients exhibited greater recuperative powers than patients he had previously observed with this type of infection. It must be remembered that such patients are usually middle-aged or elderly people. Of the fifty-two patients, fourteen left the hospital during the second week after operation, twenty-eight during the third week, nine during the fourth week and one (who had had petrositis) during the seventh week. None had significant postoperative complications. After leaving the hospital they were carefully observed by the resident staff or attending physicians for at least three months, and they remained entirely well. We believe that such patients who are free from symptoms for three months after mastoidectomy and whose mastoid wounds and middle ears are healed at the end of that time do not acquire any intracranial complications. Thus, in only two of the vaccinated patients could death be attributed to meningitis which directly complicated a mastoid infection—a mortality rate of 4 per cent.

Of 964 patients admitted to the Mount Sinai Hospital with acute mastoiditis during the ten years (from 1921 to 1931) prior to this work, forty had mastoiditis due to infection with the type III pneumococcus. Of these, thirteen died of meningitis—a mortality rate of 32.5 per cent. (The mortality rate for the previous five years, from 1927 to 1931, was 22 per cent.) In one patient meningitis became evident during the first week after operation, in two at the end of the first week, in

three during the second week, in four during the third week (one of whom had also had a brain abscess), in two during the fourth week and in one, three months after operation

Data on the experiments conducted with the object of demonstrating antibodies for *Pneumococcus* type III in the blood serum of our patients presumably resulting from vaccination are omitted from this report. It is sufficient to state that agglutinin, precipitin and complement fixation tests failed to show the formation of antibodies and that it was impossible to confer passive immunity on mice. But, as already mentioned, it has been conclusively shown that immunity to *Pneumococcus* type III infections can exist without the presence of these antibodies in the blood serum. It is probable also that an active cellular immunity may exist without demonstrable increase in humoral antibodies in the blood stream. The immunity may be due to increased cellular and general resistance rather than to the formation of new protective substances.

As the otologic service has been under the guidance of the same chief during the past sixteen years, clinical management and operative technic have not been factors in influencing the mortality rate of the cases observed during the past five and one-half years. We are well aware, nevertheless, that our cases constitute too small a group from which to draw definite conclusions. We also realize that the *pneumococcus* type III might have been a milder organism during the past five and one-half years and that the lower incidence of cerebral complications in our vaccinated patients might have been merely fortuitous. However, in view of the immunologic success obtained with *pneumococcus* vaccine in animals and human beings by reliable experimentation, we feel that further trial of this kind of simple prophylactic therapy is warranted.

12 East Eighty-Sixth Street

ABSTRACT OF DISCUSSION

DR. RUSSELL L. CECIL, New York. The two organisms feared about the oral cavity or the ears are *Streptococcus haemolyticus* and the type III *pneumococcus*. Both of these organisms produce a highly fatal pneumonia and a very fatal form of meningitis. Unfortunately, during the winter months both organisms are often present in the carrier state. From 11 to 12 per cent of healthy persons carry the type III *pneumococcus* in their throats and probably 40 or 50 per cent carry the hemolytic streptococcus during the late winter and spring months. With respect to prophylactic vaccination against the type III *pneumococcus*, this organism does not lend itself so readily to vaccination experiments as do some of the other types. That has been found true in manufacturing horse serum against the type III *pneumococcus*. It is hard to immunize a horse against the type III *pneumococcus*. It is hard to immunize man and the small laboratory animals presumably because this organism has a very thick capsule, but it can be done, as I have shown on monkeys and others have shown with rabbits and various animals. It can be done in several ways. A very high immunity was obtained in monkeys by intratracheal injections of vaccine. One can vaccinate by intradermal injections, as the speaker reported, quoting from Kolmer. However, this seems the least desirable method of vaccination, because, in experimental work, intradermal injections are apt to sensitize. Swift pointed out several years ago that intradermal injections sensitize and intravenous injections immunize. I would like to suggest to Drs. Goldman and Herschberger that they try giving these patients small intravenous injections because of the quick results obtained, and because one can give the type III *pneumococcus*, in fact any *pneumococcus*, intravenously without producing much reaction. Another suggestion I should like to offer is that they use autogenous vaccines, because I have found that there are biologic differences in these type III

strains. Some of them give much better protection than others. So I should advise either autogenous or at least a polyvalent type III vaccine. This is an intriguing piece of investigation, which ought to lead to wider studies. Putting myself in the place of the patient, if I had to have any operation around the throat or the nose or the ear I would be particularly interested in knowing just what pathogenic organisms I was carrying before I had the operation.

DR. W. E. GROVE, Milwaukee. The terms *Streptococcus mucosus* and *Pneumococcus mucosus* have been discarded in this paper for the much better designation of *pneumococcus* type III. It has been known for many years that this organism was a very treacherous invader of the mastoid, treacherous particularly because of the danger of a meningeal complication. This paper is not the authors' first on the subject. In February of 1935 they reported on the results of vaccination of twenty-seven patients with mastoiditis due to *pneumococcus* type III infection admitted to Mount Sinai Hospital, New York. The present paper deals with sixty-one cases, including the cases reported in the original paper. These are contrasted with forty cases admitted to the same hospital between 1921 and 1931, in which no protective vaccination had been employed. The reduction in the mortality from meningitis from 32.5 per cent in the earlier group to 4 per cent in the vaccinated group should command our attention. Goldman and his co-workers were unable to find any antibodies in human serum after vaccination. Julianelle, on the other hand, was able to demonstrate heterologous antibodies in the serums of all his rabbits. It occurs to me to ask whether Goldman and his associates looked only for the type-specific antibodies or whether they also looked for the heterologous species-specific antibodies. It also occurs to me to inquire whether it is the opinion of the authors that all the cases of meningitis encountered were the direct complications of the mastoiditis, or whether some of them might be regarded as hematogenous in origin.

DR. ISIDORE FRILSNER, New York. In infancy, *pneumococcus* type III disease in the bone is not any different, so far as its severity or the occurrence of complications is concerned, than any other infection. It is only when the temporal bone becomes pneumatized, and particularly in the infection of middle life and thereafter, that this particular type of infection increases in seriousness and proportionate to the lack of resistance, brought about either through age or through dyscrasia. There can be no question that in these particular cases presented by the authors adequate operation was performed. In the case in which meningitis occurred secondary to an operative trauma the pneumatic structure and the disease was followed behind the lateral, then along the posterior petrosal surface, with some of the dips of the dura that enter the bone in that situation were opened and there was a leakage of cerebrospinal fluid. All physicians who have had large operative experience will subscribe to the statement that in years the successive experiences with infection by *pneumococcus* type III have definitely demonstrated the inadequacy, the inefficiency at times, of surgical procedures alone. There is need for some other agent, particularly in view of the fact that with diminishing resistance the destruction in the temporal bone is out of all proportion to what occurs in that structure from other types of infection. I recall one petrous pyramid that was taken from a patient who had *pneumococcus* type III infection in the mastoid together with syphilis and diabetes. The destruction was out of all proportion to what one would expect. This man had a huge peribulbar abscess and a sinus thrombosis during the time that he was ambulant. He had a very extensive labyrinth, and despite the fact that his disease was progressing toward a fatal termination, the labyrinth showed reparative processes, with formation of new bone. The fact must be faced that in this type of infection in the temporal bone, and in the aged, in the diabetic, in those in whom general resistance has been weakened through either age or disease there is definite need for something more than surgical treatment. That is the chief note on this paper, its chief promise, because while the results are not definitely conclusive they point the way toward the possibility of aiding surgery by immunization.

DR. JOSEPH L. GOLDMAN, New York. I may have failed to make myself clear with regard to the type of vaccine used.

We use autogenous vaccines, except for the first dose, which is taken from a stock vaccine. This is done to save time. It is administered very often within twenty-four hours after operation, at which time the bacteriologic diagnosis is usually reported. It is true that vaccines administered intravenously are superior antigenically to vaccines administered by other routes. We have hesitated, however, to use this method because of possible constitutional reactions. I believe that most of the recent work on the subject points to the fact that intracutaneous vaccines have greater immunizing value than vaccines administered subcutaneously. With our patients we have never encountered any sensitization. I would like to repeat that with a pneumococcus type III made pathogenic by repeated animal passage it is possible to induce an active acquired immunity. With regard to Dr Grove's questions, I believe that all cases of meningitis secondary to acute mastoiditis are the result of direct extension and not metastatic in origin. We are of the opinion that patients having acute mastoiditis without involvement of the lateral sinus, or not complicated by a condition such as erysipelas or meningitis, do not have bacteremia. We did not examine the serum of our patients for heterologous or species-specific antibodies.

THE ERYTHROCYTE SEDIMENTATION RATE

THE ADEQUACY OF A SIMPLE TEST AND ITS PRACTICAL APPLICATION IN CLINICAL MEDICINE

EDWIN G BANNICK, MD
ROBERT O GREGG, MD
AND
CHESTER M GUERNSEY, MD
ROCHESTER, MINN

Although estimation of the rate of sedimentation of erythrocytes has proved to be a valuable laboratory aid in clinical medicine, it is not used as widely or as wisely as it should be used. There are two chief reasons for this. In the first place, it is erroneously regarded by many physicians as a difficult technical procedure. A survey of the voluminous literature on the subject will disclose that much of it is devoted to technicalities involved in performing and interpreting the test. The original methods used by Fahræus,¹ Westergren² and Linzenmeier³ were simple, but subsequent investigations, aiming to improve the test and eliminate error, have introduced numerous new techniques. Various types of anticoagulants, and tubes varying in length and bore, have been used. Much has been written concerning the importance of frequent readings or measurements, and various plans for charting readings have been devised. The advisability of correcting for anemia has been repeatedly emphasized, and various plans for making such corrections have been suggested. Other influencing factors, dealing with variations in temperature, deviation of the sedimentation tube from the perpendicular, and changes in the chemical constituents of the blood frequently have been noted. To the casual observer all this has made the test appear difficult and the results uncertain, and many physicians for these reasons have failed to use the test.

The second reason why the test is not more widely used is that the rate is increased in many diseases and is normal in many others. This, too, tends to make for confusion.

We have two main purposes, therefore, in the presentation of this paper: first of all, to demonstrate that a simple test such as can be performed easily by a general practitioner in his office is entirely adequate for practical purposes, and, second, to show that in those diseases in which the test has its chief value the results are reliable, fairly uniform and not confusing.

ADEQUACY OF A SIMPLE TEST

At the Mayo Clinic we have used a simple, modified Westergren test as follows. Five-tenths cc of a 3.8 per cent solution of sodium citrate in distilled water is placed in a tube, and to this is added 4.5 cc of blood that has been drawn from a vein with as little stasis as possible. After the tube has been inverted several times to insure thorough mixing, a Westergren pipet is filled to the 200 mm mark and placed in a rack in a strictly vertical position at room temperature. The height of the column of plasma is read at the end of one hour and reported in terms of millimeters of sedimentation in one hour. The importance of keeping the tube in a strictly vertical position must be repeatedly emphasized because slight deviation from this position results in a surprisingly increased sedimentation rate. Although this simple test has seemed to give clinical satisfaction, certain questions arose in our minds as time went on and as the medical literature dealing with the subject increased.

Should we make readings oftener than at the end of one hour to get the maximal information from the test? Should we use heparin as an anticoagulant instead of sodium citrate? Should a routine correction for anemia be made with each determination?

We have answered these questions to our own satisfaction after careful study. We have found that a single reading at the end of one hour is entirely satisfactory if the tube is tall enough. Packing of the erythrocytes, with corresponding slowing of the sedimentation rate, occurs, of course, much earlier in the shorter tubes, and if a short tube is used and a rapidly sedimenting blood is encountered, more frequent readings must be made in order to get a true idea of the rapidity of the rate of sedimentation. But in the Westergren tube, which is 200 mm tall, little packing occurs within the first hour, so that a single reading is entirely adequate. Charts 1, 2, 3 and 4 illustrate this point. In the work from which chart 1 was constructed sedimentation rates were calculated on the same blood but with different tubes. The same anticoagulant (0.5 cc of 3.8 per cent solution of sodium citrate to 4.5 cc of blood) was used in the Cutler and in the Westergren tubes, but heparin was used as an anticoagulant in the Wintrobe tube. The same conditions obtained in the work from which chart 2 was constructed. Rapidly sedimenting blood was used in each case to emphasize the phenomenon of packing. In the 50 mm tube, packing occurred in about twenty minutes in the case of subacute bacterial endocarditis (chart 1) and also in the case of infectious arthritis (chart 2), so that the reading at the end of an hour was practically the same as it was in twenty minutes, and unless more frequent readings were made the true rapidity of the process of sedimentation would not be determined. Packing of the erythrocytes does not occur in the 100 mm tubes as soon as it occurs in the 50 mm tubes but in the case of subacute bacterial endocarditis (chart 1) and even

Because of lack of space this article is abbreviated in THE JOURNAL. The complete article appears in the authors' reprints.

in the case of infectious arthritis (chart 2), in which a low hematocrit volume naturally delayed the time of packing, it did occur before the end of the hour. In the 200 mm tubes very little packing occurred in the first hour in either case, and therefore a single reading at the end of one hour would be adequate.

Sedimentation rates were calculated on a group of hospital patients by means of the simple, modified Westergren technic which we have described and also the method described by Rourke and Ernstene⁵ with heparin as an anticoagulant. We used the Wintrobe tube which is 100 mm in length and a higher concentration of heparin (12 mg of heparin per cubic centimeter of blood) than that used by Rourke and Ernstene, but otherwise the technic followed was the same as that used by the investigators named. The readings were made every five minutes for one hour and plotted. The straight line portion of the graph obtained was measured and recorded as millimeters of sedimentation per minute, thus taking into consideration the period of aggregation of erythrocytes as well as the period of packing. Corrections were not made for anemia. In chart 4 the modified Westergren and Rourke-Ernstene methods are plotted against each other. It is readily seen that striking correlation exists. In only a few instances is there discrepancy. Furthermore, careful analysis of the discrepancies shows that in the six cases in which the sedimentation rate was increased as determined by the modified Westergren method and was not increased as determined by the Rourke-Ernstene method, pathologic change was sufficient to cause an increased sedimentation rate and the error would seem to be on the part of the latter method. Likewise, in three of the cases in which the rate was increased as determined by the Rourke-Ernstene and not by the

question that was raised, namely, that with regard to the anticoagulant Sodium citrate in the concentration in which we have used it has seemed to be a satisfactory anticoagulant, thereby agreeing with the observation of Walton⁶. Some physicians may prefer a dry anticoagulant, especially for use in the office, because of some inconvenience in keeping a fresh solution of 18 per cent of sodium citrate. Dry potassium oxalate

Chart 4—Each black dot represents a determination of sedimentation rate on the same blood by means of the modified Westergren method in which the result is reported in terms of millimeters of sedimentation in one hour and by means also of the Rourke-Ernstene index in which the result is reported in terms of millimeters of sedimentation per minute.

(2 mg per cubic centimeter of blood) has seemed to be satisfactory, and it has an additional advantage in that the same blood can be used for the sedimentation test as for blood chemical determinations. Wintrobe and Landsberg⁸ expressed the belief that the mixture of ammonium oxalate and potassium oxalate is a better anticoagulant than potassium oxalate alone. They recommended 6 mg of ammonium oxalate and 4 mg of potassium oxalate to 5 cc of blood. At any rate, the problem of a satisfactory anticoagulant is simple enough and the physician can decide which one he prefers for his particular type of practice and can familiarize himself with it. We have been satisfied with the sodium citrate solution which we have described.

The question of the effect of anemia on the sedimentation rate has been much discussed, but the effect of various types and degrees of true anemia on the rate never has been satisfactorily studied. Little has been added since Fahraeus¹ demonstrated that by diluting cells with plasma the rate was accelerated. Gram,⁹ by experiments in concentration and dilution, worked out a chart for hemoglobin values from 70 per cent to 120 per cent. Walton⁶ calculated a set of corrections for anemia by dilution experiments with the erythrocyte count as standard. Rourke and Plass¹⁰ and later Rourke and Ernstene,⁵ using hematocrit readings with heparin for standards of comparison, worked out a correction chart based on experiments in which they concentrated and diluted blood obtained from both normal individuals and those suffering from disease.

Charts 1 and 2—Determinations of the sedimentation rate with three tubes of different lengths. Cutler tube 50 mm high. Wintrobe tube 100 mm high. Westergren tube 200 mm high. Chart 1 blood of a patient who had subacute bacterial endocarditis. Chart 2 blood of a patient who had infectious arthritis.

modified Westergren method the patients had bleeding duodenal ulcers, and the increased rate recorded by the uncorrected Rourke-Ernstene technic was probably due to the anemia, the corrected rate in each case was normal. Therefore, only in case H (chart 4) did the simple test fail to give satisfactory information. This would seem to offer further proof that a single reading at the end of one hour is entirely adequate when the Westergren tube is used, and it also answers the second

Wintrobe and Landsberg⁸ made similar experiments, using only normal blood with dry potassium oxalate as the anticoagulant

There is no doubt that anemia has an accelerating effect on the sedimentation rate, but in our clinical experience we have found that this effect may vary with the type of anemia and the type of anticoagulant as well as with the degree of anemia. Our impression is that the sedimentation rate is in general not quite as fast in anemia as the dilution experiments would indicate and that the various corrections for anemia tend toward overcorrection. In forming this impression we have studied the corrected and uncorrected rates (Rouike-Ernstene method) of a considerable number of anemic patients who had diseases which are practically always characterized by increased sedimentation rates, in these cases the uncorrected rates were high and the nonfilament leukocyte counts were increased, but not infrequently the corrected rate gave normal readings. Further, we have made determinations of sedimentation rates in a group of cases in which anemia, owing to acute loss of blood, was present. Chart 4 represents such studies in ten cases of bleeding duodenal ulcer. Sedimentation rates were determined by two methods at each calculation for one a 200 mm Westergren tube was used and sodium citrate was employed as the anticoagulant and for the other a 100 mm Wintrobe tube was used and heparin was employed as the anticoagulant, as previously described. Study of chart 4 will show that in the first place erythrocytes of heparinized blood usually undergo sedimentation more rapidly in these cases of acute bleeding than they do in citrated blood and, second, that in citrated blood the sedimentation rate was not increased as much, in most instances, as the degree of anemia (determined by the hematocrit volume) would have led one to expect, according to the various methods of correction that have been devised.

One of us¹¹ has reported the results of sedimentation tests on rabbits made anemic by bleeding and allowed to recover. In this work also the sedimentation rate in the blood of anemic rabbits was not as fast as dilution experiments would have indicated. Therefore, although we appreciate that correction for anemia must be taken into consideration, we believe that too much emphasis has been placed on the necessity of making such routine corrections in every case. Many physicians have been led to believe that without calculated correction for anemia the test is misleading and therefore many do not use the test because such corrections make it considerably more complicated than otherwise.

From a practical standpoint, routine correction in each case is unnecessary and, as we have indicated, may even give false corrections. In a large percentage of the cases in which the sedimentation rate has its chief clinical value it will not be necessary to make any actually calculated correction for anemia because the uncorrected rate usually is either normal or significantly abnormal, without any calculated correction. If the sedimentation rate is only slightly increased and the patient is significantly anemic, the assumption can be made with reasonable accuracy that the slight increase in the sedimentation rate is accounted for by the anemia—at least that is what the correction charts would show.

It is only in cases in which anemia is slight and there is a slight increase in the sedimentation rate or in cases in which anemia is moderate or marked and there is a

moderate increase in the sedimentation rate that interpretation of the reading of the sedimentation rate becomes difficult. This situation arises rather infrequently in cases encountered in the practice of general medicine in which the sedimentation rate has its chief practical application. When it does arise, the physician either can discount the value of determination of the sedimentation rate in that particular case or he can make correction for the anemia by whatever method he chooses, keeping in mind the possibility of the tendency toward overcorrection.

PRACTICAL VALUE OF THE TEST IN CLINICAL MEDICINE

So much for the adequacy of the simple determination of sedimentation rate which we have described. Now as to its practical value in clinical medicine. Much has been written concerning the sedimentation rate in a great many diseases. Numerous articles have designated those diseases in which the sedimentation rate is likely to be increased, those in which it is likely to be normal and those in which the results are variable. Such a grouping is very difficult, can be only relatively accurate and may make the test appear so nonspecific

and variable as to have little clinical value. We are not much interested in the sedimentation rate in diseases such as thyrotoxicosis, hypertension, lead poisoning, various types of skin disease, nephritis, congestive heart failure, jaundice and many others like this, in which the sedimentation rate is extremely variable owing to many complicating factors and in which it adds little to the clinical picture or may only cause confusion.

We are interested in what the sedimentation rate is in those diseases in which it is of real diagnostic and prognostic value and in which the results fortunately are not confusing. We believe that the practical value of the determination of sedimentation rate in general medicine is threefold: (1) to indicate the presence of disease, (2) to indicate the activity and progress of diseases such as tuberculosis, pelvic inflammatory disease, acute cholecystitis, rheumatic fever, infectious arthritis, pneumonia and other thoracic infections and suppurations, Hodgkin's disease, acute febrile illnesses and acute coronary thrombosis, and (3) to aid in differential diagnosis.

To indicate the presence of disease, the test is entirely nonspecific and must be properly interpreted lest it give false sense of security. As has been stated repeatedly and as every one who has had much experience with the test knows, a normal sedimentation rate does not mean that the patient has no disease. In many diseases the sedimentation rate is normal. A normal sedimentation rate in a case in which the evidence is of a functional disorder gives the physician reassurance, as it does also in a case of questionably active tuberculosis, of systemic infection or of back pain when the patient

Chart 5.—Sedimentation rate in ten cases of bleeding duodenal ulcer variation in sedimentation rate according to hematocrit volume

11 Clegg, R. O. The Sedimentation Rate in Experimental Anemia (Rabbit). *J. Lab. & Clin. Med.* 22: 786-795 (May) 1937.

is elderly and might have metastatic cancer. In all such instances and in other similar instances, however, the physician should not place too much reliance on the sedimentation rate and should regard it simply as another link in the chain of evidence against organic disease, particularly against systemic organic disease, in that particular case.

On the other hand, when the sedimentation rate is increased the physician can be certain that some abnormality exists. Pregnancy is the only physiologic process that is accompanied by significantly rapid sedimentation of the erythrocytes. Occasionally the physician will be unable to find the cause of the increased

TABLE 1—Sedimentation Rate

Diagnosis	Cases	Sedimentation Rate Mm in 1 Hour			Mean
		1-15	16-24	25+	
Fibrositis	100	73	16	11	11.6
Atrophic arthritis	100	3	6	91	71.6
Hypertrophic arthritis	25	25			9.2
Skeletal metastasis	58	3	3	52	74.7

sedimentation rate even after careful study. In such rare instances he must advise the patient according to his clinical judgment and should not become unnecessarily confused, yet he should assume that the increased sedimentation rate is probably a correct indication of some abnormality and he should try to keep in touch with the patient until the sedimentation rate has reached normal or until the reason for the increased rate has become apparent.

The sedimentation test is of practical value also as an aid in determining the activity and progress of certain diseases and thus is a great help in planning proper treatment. We have mentioned those diseases in which we have found the test to be of particular value in this regard. Its use in tuberculosis and pelvic inflammatory disease needs little comment because so much already has been written on those subjects and because acceptance of its value has been so widespread. Cutler¹² stated that as an aid in investigating activity the sedimentation test is more reliable than the temperature curve, pulse rate or gain in weight, the three major guides in the treatment of tuberculosis. At present the sedimentation test is a routine procedure in most institutions specializing in the care of tuberculous patients.

The sedimentation test has played an important part in the present day conservatism in the management of pelvic inflammatory disease. In the past the residual activity in such cases was not appreciated, and therefore the rigid management was not maintained long enough. This resulted in numerous recurrences and exacerbations of the process until too often surgical operation was required. Operation also was performed frequently when the process was too active, and radical measures often were necessary, with increased operative risk and poor results. At present the sedimentation test is widely used to demonstrate activity in cases in which the process otherwise would seem to be quiescent. Thus, by continuation of rigid management and observation until the sedimentation rate is practically normal, and by the addition of newer methods of applying heat locally and of inducing fever artificially, the vast majority of patients who have acute pelvic inflammatory disease, particularly of the gonorrheal type, are so much improved that surgical operation is not necessary.

In those cases in which medical management fails and surgical operation is necessary, the sedimentation test again provides a measure of the activity of the process, and the surgeon usually postpones operation until the sedimentation rate has returned nearly to normal, at which time a more conservative operation can be performed with less risk and with prospect of better end results.

Likewise in acute cholecystitis the sedimentation test provides a reliable guide to the activity of the process. The fever and leukocytosis may have subsided, and the abdominal tenderness and rigidity may have markedly diminished, but if the sedimentation rate remains elevated the surgeon can anticipate considerable activity. Furthermore, if the sedimentation rate, instead of gradually falling begins to rise, the surgeon can suspect some complicating factors which may require prompt surgical intervention. In rheumatic fever also the test provides the most accurate guide as to activity. The sedimentation rate usually remains increased for a considerable period after the elevated temperature has subsided and after involvement of the joints has disappeared. It is generally agreed that the patient should remain quiet until the sedimentation rate has become practically normal. In this way complications and exacerbations are frequently avoided. A rising sedimentation rate in the course of the illness should put the physician on the lookout for some complication such as pericarditis.

The sedimentation rate is increased in gout in the stage of active involvement of the joints but returns to normal between attacks. In infectious arthritis the sedimentation test again acts as a sensitive indicator of the activity of the process and is a valuable laboratory aid to the physician in managing such a case. The sedimentation rate is significantly increased in well developed pneumonia and subsides slowly and gradually as resolution of the pneumonic process continues. This helps the physician to determine how soon the patient

TABLE 2—Four Early Cases of Acute Pelvic Inflammatory Disease (Gonorrheal)

Case	Duration of Pain Days	Sedimentation Rate Mm in 1 Hour	Leukocytes per Cu. Mm	Polymorpho nuclear Leukocytes per Cent	Temperature Degrees F
1	1	7	24,000		99.8
	2	56	25,000	91	101.1
	3	83	13,000		98.4
2	1½	22	15,200	90	100.5
	2	41	18,000	91.5	103.2
	9	76	11,000		100.5
3	2	16	11,900		99.6
	3	38	9,700		100.5
4	5	17	22,500	84.5	100.0
	6	47	13,600	79.5	99.5
	7	58			98.4

should resume activity. If, instead of gradually falling, the sedimentation rate begins to rise, some complication such as beginning empyema should be suspected. In other forms of thoracic infection and suppuration the test aids in determining whether the process is subsiding, extending or remaining practically unchanged.

In Hodgkin's disease and lymphoblastoma the sedimentation rate is usually significantly increased. It therefore is of some aid in differential diagnosis of these diseases and when patients return for reexamination an increased sedimentation rate suggests that the process is still active and thus may help in the decision as to whether further roentgenologic treatment is advisable.

In acute febrile illnesses the test aids in detecting the early onset of complications. In many acute fevers

¹² Cutler, Jacob. The Graphic Method for the Blood Sedimentation Test. Presentation of a 1 cc. Technique and Other Important Modifications and Suggestions. *Am. Rev. Tuberc.* 19: 544-558 (May) 1929.

the sedimentation rate is not increased in the early stages but tends gradually to rise and then slowly to fall. Any sudden or striking increase in the sedimentation rate under such circumstances suggests the onset of some complication.

The test is of some value also in following the progress of a patient who has had acute coronary thrombosis.

In the third place, the sedimentation test may provide valuable aid in differential diagnosis. When used in this way, much caution must be exercised because the test is fundamentally nonspecific and its real function should be to indicate the presence of disease and to allow the course of disease to be followed. However, as a result of a large clinical experience with this test, in many diseases, we have found it to be of great practical value in the differential diagnosis of several groups of cases, as follows:

It may aid in distinguishing benign from malignant conditions, but the test must not be relied on too much in this regard. We have seen patients who had carcinomas of various types and sizes, and who even had regional and distant metastasis, whose sedimentation rate was perfectly normal. Usually, however, the sedimentation rate is increased in the presence of malignant conditions, particularly when the lesion is of the ulcerating type.

In skeletal malignancy, particularly when it is metastatic, the sedimentation rate is almost always increased and usually is markedly increased. In a group of fifty-eight cases in which there was skeletal metastasis, which we have been studying and which will be reported soon,¹³ in fifty-two sedimentation rates were more than 25 mm in one hour and in only three were sedimentation rates less than 15 mm in one hour. In most instances the sedimentation rates were high, so that the mean in the fifty-eight cases was 74.7 mm in one hour (table 1). The frequency with which a markedly increased sedimentation rate occurs when skeletal metastasis is present is often a point of great value in the diagnosis of such a condition. A case of suspected metastatic skeletal malignancy, in which there is a significantly increased sedimentation rate that cannot be accounted for on any other basis, must be considered to be an instance of skeletal metastasis until it is proved otherwise, even though roentgenograms fail to reveal metastasis. In several such cases that we have seen, subsequent roentgenograms have revealed the skeletal metastasis. If, in addition to the increased sedimentation rate, myeloid immaturity is discovered in examination of the blood smear, and the total leukocyte count is normal or nearly normal, the diagnosis of skeletal malignancy can be made with a high degree of accuracy.

The sedimentation test is of great value also as an aid in the differential diagnosis of various forms of arthritis. As is shown in table 1, in ninety-one of 100 cases of atrophic arthritis (infectious arthritis) reported by Slocumb,¹⁴ sedimentation rates were more than 25 mm and the mean rate was 71.6 mm in one hour. In only three cases was the sedimentation rate less than 15 mm in one hour, and these were all cases in which there was very little activity. In comparison with this, Slocumb noted that in 100 cases of fibrositis that were carefully selected from the standpoint of diagnosis (table 1) in only eleven were sedimentation rates more than 25 mm in one hour. The mean was 11.6 mm in one hour. In seventy-three of the 100 cases

the sedimentation rate was less than 15 mm in one hour. In simple hypertrophic arthritis the sedimentation rate is rarely increased. It generally has been assumed that hypertrophic arthritis causes a slight elevation of the sedimentation rate in about 2 per cent of the cases, but in the twenty-five cases, records of which we took at random from our files, the sedimentation rate was normal in each instance (table 1).

Finally, determination of the sedimentation rate has proved to be valuable in the differential diagnosis of acute appendicitis from other acute abdominal diseases which simulate it. Lesser and Goldberger¹⁵ were the first to show that the sedimentation rate was normal in the presence of acute appendicitis without rupture, even though the appendix was gangrenous or markedly suppurative. Prior to the publication of their article it had been stated repeatedly that the sedimentation rate was normal in the presence of simple catarrhal appendicitis, but the assumption apparently had been that in association with gangrenous or suppurative appendicitis the rate was likely to be somewhat increased. Repeat-

Chart 6—Sedimentation rate in acute appendicitis and acute pelvic inflammatory disease

edly we have been able to confirm Lesser and Goldberger's observations. In the past two years we have made determinations of the sedimentation rate in nearly all cases of acute appendicitis that we have encountered and we have not noted a single case in which the sedimentation rate was definitely increased as a result of the appendicitis unless the appendix had ruptured. In chart 6 we have recorded the sedimentation rates in a selected group of these cases. The patients were all seen by the senior author and were selected because they exemplified extremely marked acute appendicitis. In each instance the appendix was either markedly gangrenous (grade 4) or markedly suppurative (grade 4) or perforated. The diagnosis was confirmed in each case at operation or at necropsy.

If 20 mm per hour is the very upper limit of normal for the sedimentation rate, according to the method we have used and described, chart 6 will show that the sedimentation rate was normal in all except two cases of appendicitis without rupture. In one of these the sedimentation rate was 80 mm in one hour but the patient had acute gonorrheal salpingitis as well as acute appendicitis, and the increased sedimentation rate undoubtedly was due to the former. In the other case the sedimentation rate was 28 mm in one hour but the patient's erythrocyte count was 3,240,000 per cubic millimeter of blood and we were certain that the anemia

¹³ Kaump, D. H., Bannick, E. G. and Heck, F. J. Unpublished data.

¹⁵ Lesser, Albert and Goldberger, H. A. The Blood Sedimentation Test and Its Value in the Differential Diagnosis of Acute Appendicitis. *Surg., Gynec. & Obst.* 60: 157-166 (Feb.) 1935.

could account for the slightly increased rate without even making any actual correction, a point which we have made previously

Our observations, therefore, have been that acute appendicitis without rupture does not cause an increased sedimentation rate. However, this does not mean that because the sedimentation rate is increased the patient cannot have appendicitis. It simply means that such an increased sedimentation rate is due to something other than the appendicitis. The physician, therefore, must continue to use his clinical judgment. He must not rely entirely on any laboratory test and he must give the patient the benefit of surgical operation in a questionable case such as the one to which reference has been made in which the patient had both acute appendicitis and acute salpingitis. Fortunately, such an occurrence as this is rare, as chart 6 will show. Furthermore, appendicitis with rupture does not immediately result in an increased sedimentation rate. In chart 6 are represented four such cases in which sedimentation rates were perfectly normal, however, as peritonitis develops the sedimentation rate soon rises, although it usually does not go as high in the cases in which there is general peritonitis as it does in those in which abscess develops. Lesser and Goldberger further stated that the consistently normal sedimentation rate in appendicitis was of particular value in the diagnosis of acute appendicitis, because in all other conditions which produced the clinical picture of acute surgical conditions of the abdomen the sedimentation rate was definitely abnormal. In our experience this statement is true of most cases but not of all cases, and the exceptions are very important. Acute pelvic inflammatory disease offers the most frequent and difficult problem in differential diagnosis from appendicitis. In most patients with acute pelvic inflammatory disease admitted to the hospital, the sedimentation rate is significantly increased, and this provides an extremely valuable differential point between the two diseases (chart 6). However, in certain cases of acute pelvic infection the sedimentation rate may be normal when the patient is first examined. This is undoubtedly due to the fact that the patient is examined soon after the onset of symptoms or that the infection is an initial and mild one. In most of the other cases the infection has been present for some time before onset of the pain¹⁶ (chart 6).

Chart 6 shows the sedimentation rates in a group of cases of acute pelvic inflammatory disease that we have encountered. In two cases the condition was postabortal and in all the others there were acute gonorrheal infections, proved by cultures on chocolate blood agar. The sedimentation rate was significantly elevated in all but four cases. Table 2 shows that these cases all represent an early stage in the infection and that in each case the sedimentation rate rapidly increased in spite of the fact that the leukocytosis was diminishing. The practical point to be made is that the sedimentation rate in acute pelvic inflammatory disease is usually, but not always, increased, and therefore a normal sedimentation rate does not exclude this disease. The same is true of the other acute abdominal conditions such as acute cholecystitis and acute pyelitis or pyelonephritis. In most such cases in which patients are admitted to the hospital the sedimentation rate is significantly increased and this fact serves as a valuable aid in distinguishing these conditions from acute appendicitis but occasion-

ally the sedimentation rate will be found to be normal, especially when the patient is examined early in the course of the illness.

If these exceptions are kept in mind, the sedimentation test will be found to be a very valuable laboratory aid in the differential diagnosis of acute abdominal diseases, particularly those which simulate acute appendicitis.

CONCLUSIONS

We hope that we have been able to prove the following points:

1 If the sedimentation test is to have widespread use in the physician's office as well as in the hospital, the test must be simple.

2 Such a simple test is entirely adequate for practical purposes if certain facts are kept in mind. If a single reading is taken at the end of one hour, a tube such as the Westergren tube, which is 200 mm tall should be used. Shorter tubes may require more frequent determinations if the true rapidity of the sedimentation process is to be determined. The tube must be kept in a strictly upright position. Anemia tends to accelerate the rate of sedimentation, and allowance must be made for this fact, but a routine correction for anemia in each case is unnecessary.

3 When the use of the sedimentation test is restricted to those cases in which it has its chief clinical value, and when the limitations of the test are recognized, it will continue to be an extremely valuable laboratory aid in clinical medicine.

SOME PHASES OF POSTGRADUATE INSTRUCTION IN OPHTHALMOLOGY

WALTER R. PARKER, M.D., Sc.D.

DETROIT

In 1929 I prepared a report for the International Congress of Ophthalmology on the method of undergraduate and postgraduate teaching in Great Britain and her dominions and in North and South America. The report as it pertains to the undergraduate teaching in this country need not concern us here. There is one point in the postgraduate teaching in this country, however, that may be of interest. Questionnaires were sent to all the class A colleges, requesting a statement concerning the facilities for postgraduate instruction in ophthalmology, and replies were received from forty. Of these, seven were reported as offering a systematic postgraduate course in ophthalmology. It is quite impossible to state definitely the number of institutions in which postgraduate training is given for the reason that, in the classification, some reports include only those giving announced courses, while others include those giving instruction to the resident staff. The latter, it seems to me, should be included among those giving graduate work if a comprehensive course is given, even though the number privileged to take the course is limited. This report was made from data collected seven years ago and the situation may be somewhat changed.

When I started to collect material for this address I had in mind to attempt a detailed study of the methods of instruction in the institutions in which it was reported that advanced courses in ophthalmology

16 Smith, C. T., Harper, Thelma, and Watson, Anna. Sedimentation Time as an Aid in Differentiating Acute Appendicitis and Acute Salpingitis. *Am. J. M. Sc.* 189, 383-387 (March) 1935.

Read before the Section on Ophthalmology at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, June 9, 1937.

were given I soon realized, however, that the important question before us today is not how the course of instruction is conducted in certain institutions but rather what steps might be taken to increase the number of centers where adequate instruction might be given and that, perhaps, it is more a question of organization than of curriculum. I recently had made a list of names of all the ophthalmologists, and ophthalmologists and otolaryngologists listed in the last American Medical Directory, the names to appear in the new directory to be issued by the International Congress of Ophthalmology. There were, in all, 7,200 names recorded as practicing ophthalmology alone or ophthalmology and otolaryngology. As the names were arranged alphabetically, it is impossible to state definitely the number registered as ophthalmologists. There are ninety-five residencies in ophthalmology approved by the Council on Medical Education and Hospitals, and according to Dr Lancaster there are about 500 students contemplating training in ophthalmology. When one compares the number of ophthalmologists and ophthalmologists and otolaryngologists listed in the directory with the number certificated, the significance of the task undertaken by the board is evident.

It is quite impossible to think of the subject of education in ophthalmology, as it has developed during the past twenty-five years, without a keen sense of appreciation of the results accomplished by the American Board of Ophthalmology. I was not a member of the original board and so do not hesitate to pay my respects to the original members and to acclaim my admiration for the wisdom and foresight they displayed in the organization and administration of the affairs of the board. It was pioneer work, and the results were not accomplished without some opposition. From the first the deliberations of the members were serious and each one gave the best of his talents. Working without precedent as a guide, the members of the board had to develop and correlate all the details. The formulation of specific requirements for certification is not so simple a problem as one might imagine and the board has been subjected to some unjust criticism for not being more definite in its specifications. What it did in establishing the requirements in training was to formulate a certain number of equivalents that would satisfy the board and treated each case on its merits. I think I am safe in saying that, in its most enthusiastic moments, little did the board realize that in such a short space of time the work it instituted would be so generally accepted, become national in scope and be sponsored by the American Medical Association. It is an accomplishment that may well make every ophthalmologist justly proud.

Whatever our ideals may be, the problem before the boards is to meet the situation as it presents itself today and to prepare for future expansion. Progress has been so rapid and the organization has become so complex that, again, time will be required to smooth out the workings of the machinery necessary to develop and coordinate all the varying interests. All ophthalmologists are familiar with the organization of the Advisory Board for Medical Specialties as it is now constituted. Some phases of the situation, as it concerns postgraduate instruction in ophthalmology, will be considered, although what I have to say might be applied to any one of the clinical specialties represented by the Advisory Board for Medical Specialties. In general, the question of postgraduate instruction as it pertains to the present organization presents two major

points: first, the formulation of requirements of the board for certification and, second, the classification and expansion of approved centers where adequate instruction will be given.

In order to acquaint those interested in coming before the board as candidates for certification, and for the benefit of instructors, the American Board of Ophthalmology has prepared a syllabus to indicate to candidates what ground they are expected to cover in the study of the subjects required and, for teachers, courses of study more extensive than are at present commonly offered. If to these plans are added a classification and suggested organization of the clinics where adequate instruction may be obtained, the whole will not only encourage those who are now offering sufficient training but lead to the development of other teaching centers. The members of the board are all practical men with teaching experience, perfectly familiar with conditions as they exist, and certainly they will not be unreasonable in their requirements. The requirements can be raised as the teaching facilities will warrant. The length of time required in preparation might not be the same in all the specialties but, as Dr Lancaster¹ says, "In the end each board must be admitted to be the best judge of the standards for its own specialty."

The increasing appreciation of the dependence of ophthalmology on the general medical examination is well shown by the passing of the isolated eye hospital. To meet this situation the special hospitals are either adding a staff representing the essential branches of medicine or are becoming an integral part of a medical center. In many institutions the recognition of the importance of certain specialties has resulted in the establishment of separate departments. Just what determines when a branch of medicine or surgery should be given a special department is difficult to say. Apparently, those that have been so recognized in recent times have been brought about more through the pre-eminence of individual workers than through any sympathetic plan on the part of the governing bodies. Undoubtedly, more progress has been made in every instance when a certain autonomy has been granted than would have been the case had the department remained submerged. I would suggest that, when the Council on Medical Education and Hospitals makes its inspection of clinical centers, the attitude of the institutions toward the specialties be considered. This is important for the reason that the services of the best teachers will not be available unless the position as senior member of the staff carries with it the dignity and responsibility of professional and administrative authority.

While adequate clinical instruction is given in many hospitals, instruction in the basic subjects is given in only a very small number. The suggestion has been made that intensive courses in the basic subjects be given in centers to be established in various parts of the country. If centers could be established and maintained where the basic subjects could be given, it might be ideal, but such opportunities will not, in all probability, be available for some time to come. I am well aware of the fact that some educators believe that clinical teaching should not be given until after the basic subjects are taught. On the other hand, there is a tendency to incorporate clinical teaching in the pre-clinical year in undergraduate courses. Replies to inquiries concerning instruction in the basic subjects

¹ Lancaster W. B. Educational Standards of Ophthalmology That Must Be Met at This Time. *Arch. Ophth.* 17: 401 (March) 1937.

revealed the fact that there was no general understanding as to how much instruction in these subjects should be required to qualify an ophthalmologist. This is a question for the board to determine. The present system of presenting instruction in the basic subjects during the period of clinical training has worked satisfactorily for the most part, and perhaps for the present it should not be discouraged and an effort should be made to arrive at a more general agreement as to the exact requirements in the fundamental subjects.

The main question before us today is: How can the clinical and teaching material we have at hand be utilized in order to increase the number of teaching centers?

The epoch making results accomplished by the Council on Medical Education and Hospitals in the classification of medical schools is well known. My understanding is that a similar classification of the available teaching centers in the specialties is to be made. The coordination of facilities for the teaching of specialties is to be undertaken by the Advisory Board for Medical Specialties. It would seem that a practical working organization would be for the various boards to determine the requirements that could be properly enforced at any particular time, the Council on Medical Education and Hospitals to designate available teaching centers, all to be coordinated by the Advisory Board for Medical Specialties. The essential principle underlying the specifications for certification in a specialty, as well as in the classification of teaching centers, is to keep the requirements within the bounds of performance. The requirements of the board could be increased as the teaching facilities would warrant. The process should be one of evolution and not of legislation. The object is not to produce superstudents—they have an uncanny way of looking after themselves—while all the legislation in the world would not make an unborn research worker productive. The classification of institutions might include not only those that offer opportunity for instruction in all the branches required but such as offer acceptable instruction only in clinical training and those that offer work in the basic subjects. If this information was available the student could take the work in a manner most convenient to himself. It matters not where one does one's work so long as one meets the training requirements and can pass the examination.

Ophthalmology cannot be a thing apart from the field of medicine and surgery, and to be thoroughly appreciated the work must be coordinated with the essential branches of both. The most favored ophthalmic service is one that is an integral part of a general teaching hospital. The next most favored is one associated with a general nonteaching hospital or a special hospital which has an auxiliary staff covering the essential branches of medicine, surgery and dentistry. Is it not true that there are many clinics with an abundance of clinical material and efficient clinical staffs that are doing good work as far as care of the patients is concerned but where very little attention is being paid to the training of assistants? Either from lack of interest or from lack of cooperation on the part of the management, things go unchanged year in and year out. By proper organization could not many of these clinics be developed into teaching centers and thereby contribute their quota toward the solution of the educational problem? The classification of the available teaching units contemplated by the Council on Medical Education and

Hospitals should give the whole movement an added impetus that will, in the near future, lead to gratifying results.

While not offering it as an ideal plan, I should like to speak of a service with which I am familiar, the organization of which was as follows. The staff was made up of rotating and permanent members, the rotating members being on full time and the permanent members on part time. There were three members of the rotating staff, each serving for three years after one year's service in a general hospital, one year as intern, one year as junior assistant and one year as senior assistant. In addition to the regular work, one evening a week during the college year was devoted to instruction in the basic subjects, and during the senior service the one in charge quizzed the junior students, and all members of the staff assisted in demonstrating cases to the members of the section of the senior class. As a matter of fact, the plan as outlined was instituted as part of an organization designed to teach ophthalmology to undergraduate students. After the establishment of the American Board of Ophthalmology the instruction given the rotating staff members was modified to meet the requirements of the board. Throughout the entire period the reading material was suggested and frequent informal meetings of the rotating and permanent staffs were held. Each year one man was graduated who was well trained in ophthalmology and who had had some experience in teaching. The details of clinical and laboratory work need not be given, as they would vary somewhat in each clinic. To increase the available number of centers of instruction, would it not be possible, by sympathetic assistance and suggestions concerning organization and enlistment of qualified teachers, to develop similar services in many hospitals? The number of students enrolled would depend on local conditions and the term of service on the requirements of the board. In special hospitals with more than one clinic functioning daily a rotating staff might be added to each service instead of having a single staff for the entire hospital as at present. I am familiar also with the reorganization of a clinic designed primarily to awaken interest in the basic subjects. An outline of the courses was prepared by the chief of clinic, and the most promising members of the staff were selected to develop a course and to present it to the staff. In a comparatively short time an interest in the basic subjects was created that permeated the whole group. The courses were very elementary and, as so often happens, the greatest benefit came to the members of the staff who gave the course.

One cannot speak of postgraduate education in ophthalmology without considering the part played by short courses. While short courses serve as a review and may be a source of stimulation to those who take them, the benefit derived from this method of instruction cannot in any way be compared to that received in a residency or from being a member of the staff. The benefit to be derived through having clinical responsibility cannot be acquired in any other way.

There is no cause for pessimism concerning the progress of ophthalmology in this country, when one realizes the advance that has been made during the last twenty-five years. Probably the most important influence in this change has been the American Board of Ophthalmology, the activities of which not only have elevated the standards of clinicians but have had a most beneficial influence on the quality of teaching offered. An outstanding advance in the instruction offered in oph-

thalmology has been manifest through the systematic courses given to resident staffs. The rate of progress may have been slow, but there is every reason to believe that it will be greatly accelerated by the activities of the Advisory Board for Medical Specialties as sponsored by the American Medical Association.

PAIN LOW IN THE BACK AND "SCIATICA"

DUE TO LESIONS OF THE INTERVERTEBRAL DISKS

J S BARR, MD
A O HAMPTON, MD
AND
W J MIXTER, MD
BOSTON

In previously published papers,¹ attention was drawn to the role of the intervertebral disks in causing intractable "sciatic" radiation of pain from pressure of herniated disk tissue on one or more roots of the cauda equina in the lower lumbar region. At first this syndrome was thought to be rare, but investigation has revealed that a considerable number of cases previously classified as sacro-iliac or lumbosacral strain were really rupture of an intervertebral disk. This diagnosis should be considered in the study of every case of strain low in the back and "sciatica." This paper is a joint effort to correlate the information obtained from a study of fifty-eight patients with proved rupture of an intervertebral disk in the lumbar region, operated on at the Massachusetts General Hospital from 1927 to June 1937.

A detailed historical review of the literature on the intervertebral disk is beyond the scope of this paper. A fairly complete bibliography is appended to articles by Barr^{1a} and Hampton and Robinson^{1c}. The first report of injury to an intervertebral disk in modern medical literature seems to have been made by Kocher² in 1896. To Goldthwaite³ belongs the credit for first (1911) suggesting that injuries to intervertebral disks might be a frequent cause of "lumbago" and "sciatica." The surgical removal of "chondromas" of the intervertebral disk pressing on the spinal cord or nerve roots has been described by various neurosurgeons, among them Adson,⁴ Elsberg,⁵ Dandy,⁶ and Mixter.⁷ Mixter

and Barr^{1a} pointed out in 1934 that these "chondromas" were not neoplasms but were simply herniations or ruptures of normal intervertebral disk tissue into the spinal canal and that they were a frequent cause of "sciatica" and strain low in the back. They reported nineteen proved cases from the Massachusetts General Hospital. Later reports by us^{7a} have described in detail the neurologic and neurosurgical, roentgenologic and orthopedic aspects of these lesions.

SIGNS AND SYMPTOMS

The clinical syndrome of rupture of a lumbar intervertebral disk with pressure on one or more roots of the cauda equina is similar to sacro-iliac or lumbosacral strain with "sciatica." In fact, a clinical differential diagnosis in many cases is impossible. The patient is usually a healthy, vigorous man between the ages of 20 and 50 whose chief complaint is pain radiating unilaterally down the posterior part of the thigh and the posterolateral part of the calf. There may be pain in the buttock or in the lumbosacral or sacro-iliac region. There may be a sensation of numbness or tingling in the involved extremity. Bilateral radiation of pain, muscular weakness or paralysis and incontinence of urine and feces are occasionally found and indicate severe damage to the cauda equina. A history of trauma to the lower part of the back was obtained in about 80 per cent of our cases. The most common type of trauma was sustained when the patient was lifting a heavy weight and felt something "give way" in the lower part of the back. In about one half of the cases trauma immediately preceded the onset of symptoms. Almost half of our patients had a history of remissions and exacerbations of their symptoms. Practically without exception they had had prolonged conservative orthopedic treatment consisting of rest in bed, support of the back and exercises.

On physical examination, limitation of motion of the lumbar part of the spine by muscle spasm is the most characteristic observation. The usual lumbar lordosis is diminished or obliterated. Kyphosis may be present to such an extent as to simulate vertebral collapse. A fixed list ("sciatic scoliosis") of the lumbar part of the spine, which occurs toward or away from the affected side with about equal frequency, is commonly noted. Straight leg raising is limited almost always unilaterally and sometimes bilaterally. There is local tenderness over the lumbar spinous processes and inter-spinous ligament at the site of the lesion in many of the cases. There may be tenderness over the buttock, the sacro-iliac ligaments and the course of the sciatic nerve. In most cases certain positions relieve and others aggravate the radiating pain.

Neurologic changes, motor, sensory and reflex, may be totally absent in perhaps half of the cases. The most common neurologic finding is absence or diminishing of the ankle jerk on the affected side. Sensory impairment or anesthesia is rarely demonstrated because, as Foerster⁸ has shown, two or more sensory roots must be severed before anesthesia is demonstrated in the corresponding dermatome. A few patients have shown complete or partial paraplegia, the lesion being so large that it occluded the spinal canal.

If the history, physical examination and ordinary roentgenograms suggest the possibility of a ruptured

disk as the cause of intractable "sciatica," lumbar puncture is indicated. It should be done as low as possible, preferably at the lumbosacral articulation, and the first 2 to 5 cc of fluid removed should be examined for the total protein content. Elevation of the total protein content is apparently due in most instances to irritation of the nerve roots and not to a block in the circulation of the cerebrospinal fluid. If the total protein is determined on successive fractions of fluid, it is often observed that the first fraction contains much more than the last one. Hence, if the lumbar puncture is done too high, or too large a quantity of fluid is removed, a false normal value may be found. Elevation of the total protein above 40 mg per hundred cubic centimeters was present in all but six of our cases. If the content is elevated we do not hesitate in proceeding with the diagnostic use of iodized oil, but if it is within normal limits we must rely on appraisal of the clinical picture in deciding whether or not to use iodized oil.

A study of the regular roentgenograms of the lumbar part of the spine revealed no significant variation from the normal in about one half of our cases. This type

TABLE 1—Incidence by Sex and Age

Disk between 1st and 2d sacral vertebrae	1	

of examination, therefore, cannot be relied on as an indication for or against the injection of iodized oil. Narrowing of the intervertebral joint spaces, with or without formation of new bone about the margins of the joint, occurred in one third of the lesions located at the fourth lumbar disk, but it was often associated with narrowing of other intervertebral joint spaces, particularly the space between the fifth lumbar vertebra and the sacrum. Sciatic scoliosis and partial obliteration of the normal anterior lordotic curve of the lumbar part of the spine occurred in most of the cases. The familiar Schmorl's⁹ nodule in the body of a vertebra was seen only occasionally and is purely an incidental observation.

EXAMINATION WITH IODIZED OIL

The roentgenoscopic examination after the injection of iodized oil is the most important step in the diagnosis. The lesion can be accurately localized and readily demonstrated on the roentgenogram. It is necessary that the examination be done with the proper technic. In a series of over 100 cases we observed no permanent ill effects which could be attributed to the use of iodized oil in the spinal subarachnoid spaces.

Five cubic centimeters (one ampule) of iodized poppy-seed oil is injected into the lumbar canal. The

roentgen examination may be done immediately after the injection or at any time thereafter up to several months. It may be necessary to give the patient appropriate drugs for the relief of pain so that he can cooperate in the examination. The equipment for the examination consists of a tilting roentgenoscopic table and a quick change-over switch so that instantaneous roentgenograms can be taken during roentgenoscopy. The usual roentgenoscopic equipment may, however, be used with fairly good results in the study of the lower lumbar area. The advantages of films taken during roentgenoscopy cannot be overestimated. Before the examination is begun the patient is allowed to sit up for a few moments in order to collect the iodized oil as one mass in the sacral culdesac. He is then placed facing the roentgenoscopic table in the upright position and is manipulated by tilting the table under roentgenoscopic control, the oil being thus forced to flow slowly up and down the anterior aspect of the subarachnoid spaces when the patient is tilted to the horizontal or to the Trendelenburg position. Particular attention is directed toward maintaining the iodized oil in a single mass, and it is possible by this method to place the small quantity of iodized oil in practically any portion of the lumbar canal. Since the lesion to be demonstrated is a small anteriorly placed extradural nodule at the disk levels, the iodized oil must be brought into contact with the anterior dural surfaces, and in order to do this the patient must lie face down on the table. If a questionable filling defect is observed, an effort is made to obliterate it either by turning the patient from side to side or by repeating the tilting process. A constant filling defect in any region is recorded by serial roentgenograms taken in various angles of rotation of the patient. Originally the upper dorsal region was usually examined, in the belief that multiple ruptures of the disks might be present. Multiple ruptures have proved not to be the case. The upper dorsal area is now not examined when the patient has no symptoms referable to that portion of the spinal canal. It is possible that this fact may account for the infrequency of some of the untoward reactions others attribute to the use of iodized oil. The examination of the upper dorsal area is, however, carried out, when indicated, in the same manner as the examination of the upper lumbar and lower dorsal areas. Care should be taken to prevent the iodized oil from entering the skull, and this can be done by examining the cervical area only with the patient in the face-down and lateral position.

If a tilt table is not available, the normal lordotic curve of the lumbar vertebrae and the inclined plane of the sacrum may be utilized to force the flow of iodized oil toward the head when the patient lies face down on the table. By having the patient sit, the iodized oil may be returned repeatedly to the sacral culdesac. For this type of examination it is necessary that the patient be able to shift his position rapidly or that he be able to assume the face-down position quickly without remaining for an appreciable time on his side, because the iodized oil may already be above the site of the suspected lesion before roentgenoscopy is possible. It is also necessary that a quick change-over switch be available if satisfactory roentgenograms are to be taken. In this manner, without a tilting table, it is possible to examine the greater portion of the lumbar area, but it is practically impossible to obtain a satisfactory examination of the dorsal and cervical areas.

⁹ Schmorl, Georg and Junghann, Hervert. Die gesunde und kranke Wirbelsäule im Röntgenbild. Leipzig: Georg Thieme, 1932.

INTERPRETATION OF X-RAY APPEARANCES

A correct understanding of the results of roentgen examination is dependent on an accurate knowledge of the anatomy of the cauda equina and the nature of the lesion to be demonstrated. The anatomic considerations are beyond the scope of this paper, and only typical examples of the filling defects produced in the shadow of the contrast medium can be discussed. The posterior rupture of the intervertebral disk which produces unilateral symptoms consists of a rounded nodule 1 cm or more in diameter. This nodule lies just lateral to the strong central portion of the posterior longitudinal ligament and is directed toward the lamina of the vertebra (fig 1).

In figure 1 the cauda equina together with the dura are shown to have been completely removed. The intervertebral disk is covered by the ligamentous structures. The rounded nodule represents typical rupture of a disk.

Figure 2 illustrates the relation of a ruptured disk nodule to the dura and the sheathed portions of the nerve roots. The nerve roots are pressed on before

acquires its sheath. At the point of exit of the nerve root there is a triangular pouch beneath and medial to it, which fills readily with iodized oil, and these spaces have been termed the axillary pouches. They are of importance because they may be used to identify nerve roots.

Figure 4 is a roentgenogram taken with the patient in the upright position after 5 cc of iodized oil had been injected into the subarachnoid spaces. A fluid level can be seen opposite the fourth lumbar vertebra. There is asymmetrical filling of the nerve sheaths and fairly symmetrical filling of the axillary pouches. No abnormality is demonstrated. These observations were confirmed by operation. In this case the degree of filling is sufficient for a complete examination of the fourth and fifth lumbar disk areas without its being necessary to change the position of the patient. In each case we examined in which a ruptured disk was found at operation the defect was clearly demonstrated in the anteroposterior view. If no filling defect is seen in the anteroposterior view the examination is considered to show no evidence of ruptured disk. The

Fig 1—Schematic drawing of typical unilateral posterior rupture of the fourth lumbar disk. The laminae pedicles and cauda equina have been removed. The nodule projects backward toward the lamina.

Fig 2—The cauda equina covers the nodule of the ruptured disk. It is usually more easily palpable than visualized. Note the relation of nodule to nerve root and pedicle.

Fig 3—Appearance after opening of the dura. The relation of the intradural roots to the extradural mass is seen. Compare this illustration with the roentgenograms taken after the injection of iodized oil.

they leave the subarachnoid space, that is, in the area which can be readily filled by iodized oil. Note the relation of the nerve root to the base of the pedicle. The nodule is nearly always opposite the inferior portion and articulating facet of a lamina.

In figure 3 the cauda equina is in position and the dura has been opened. An extradural, anteriorly placed unilateral mass is seen displacing one nerve root markedly and its neighbor only slightly. The degree of deformity or displacement of these roots depends on the size and location of the lesion.

It is the purpose of the roentgen examination after the injection of the contrast medium to demonstrate filling defects corresponding to this rounded mass and the displaced nerve roots. If the cauda equina is normal there is symmetrical filling of the subarachnoid spaces. Iodized poppy-seed oil is a viscid substance and the space around the nerve roots is only potential, and therefore some time is often required for complete filling of the lateral portions of the subarachnoid spaces and particularly the nerve sheaths. Asymmetrical filling of the nerve sheaths is a normal observation. Each nerve root lies in contact with the lateral wall of the arachnoid membrane before it makes its exit and

lateral view is seldom of definite value because the defect is unilateral and is not usually seen in this view, being obscured by dense iodized oil which occupies the normal side of the canal. On the contrary, the lateral view may show minor pressure defects at the disk levels which are of no clinical significance and should be disregarded.

Figure 5 is the reproduction of a roentgenogram taken instantaneously during roentgenoscopy as the patient lay face down on the tilt table. One half of the iodized oil is above and one half below the fourth lumbar disk. The filling defect on the right side (marked by the arrow) is characteristic of a unilateral rupture of a disk. The filling defects produced by the compressed nerve roots are seen in the upper lateral margin of the defect, and the convex medial defect corresponds to a medially displaced nerve root. Compare this illustration with figure 3. Large defects in the shadow are produced by large lesions but it does not follow that small filling defects are produced by small lesions because the nodule may extend laterally beyond the shadow of the iodized oil.

In figure 6 the defect is unusually large and simulates an intrinsic tumor, but in the lateral view it could be

seen to occupy the anterior aspect of the cauda equina opposite the disk area. There is complete filling of the subarachnoid spaces opposite the body of the fourth lumbar vertebra above the lesion, but the root sheaths show little filling. The examination was done with the patient in the upright position. The filling defect proved to be a rather large unilateral rupture of the intervertebral disk. Figures 5 and 6 represent ruptures of the disks between the fourth and fifth lumbar vertebrae, and it is thought that all clinically important ruptures of the disk at this and higher levels can be demonstrated in the manner described. Ruptures of the disk between the fifth lumbar vertebra and the sacrum are more difficult to demonstrate, because of the anatomic relationship, for example the first sacral root may cross the disk outside the area containing the iodized oil and therefore not be demonstrable. This condition however, did not occur in our series of cases.

A typical unilateral rupture of the fifth lumbar disk is illustrated in figure 7. The character of the defects is quite similar to those seen elsewhere in the lumbar area, but the defects are often smaller and in some instances can be visualized only on the roentgenogram. It is therefore advisable that roentgenograms be taken during fluoroscopy as the iodized oil crosses each disk area. The fifth disk area can usually be more accurately examined several days after the oil has been injected because more complete filling of the nerve

sheaths and lateral portion of the canal will take place. For this reason we usually reexamine within one or two weeks all patients whose examinations gave negative results.

The rupture that is seen in figure 7 definitely involves the first sacral root but may also compress the second and third sacral roots.

THE ACCURACY OF ROENTGEN EXAMINATION WITH IODIZED OIL

The filling defect of the ruptured disk fragment was demonstrated in each of a consecutive series of thirty-one patients examined with iodized oil. In one of this series the defect was present but was overlooked. An outright diagnosis of ruptured intervertebral disk was made in twenty-three cases.

When the lesions were unusually large or caused a complete block they were more commonly interpreted as due to tumor. Fractures of the laminae thickening of the ligamentum flavum and arachnoiditis have pro-

duced confusing pictures with iodized oil. One exploration after a positive roentgen diagnosis and six after a negative diagnosis gave negative results.

OPERATIVE TECHNIC

We believe that this lesion tends to weaken the spine and that exploration of the spinal canal will weaken it still further. Therefore, we plan our approach to preserve the strength of the spine as much as possible and follow laminectomy by a bone graft if the patient does heavy work.

It is not necessary to remove more than one or at most two laminae if localization has been accurate, and the lamina should be resected widely only on the side of the lesion. The bulging mass is felt by palpating the lumbar sac. If it is situated far out toward the intervertebral foramen, the dural sac is retracted toward the midline until it is exposed. If the mass is in the midline the dura is opened as usual for the removal of a tumor of the cord and then opened again anteriorly over the mass. As the extruded fragment lies anterior to the posterior longitudinal ligament the latter structure is incised, and then the mass of fibrocartilage is easily removed. It frequently lies free, with no attachment to the edge of the disk. The iodized oil is then removed, the bone graft placed and the wound closed as usual. A more complete discussion of the surgical technic will be found in a forthcoming paper to be published in the *Annals of Surgery*.

Fig 5—Typical filling defect produced by unilateral rupture of the fourth lumbar disk. The two serrations at the upper margin of the defect are produced by compressed nerve roots within the subarachnoid space. The iodized oil is equally distributed above and below the disk level when the patient is face down.

HISTOLOGY

Microscopic examination of the removed specimen reveals that it is identical with the normal intervertebral disk. Sometimes it is from the annulus fibrosus and sometimes from the nucleus pulposus, often elements of both tissues are present.

END RESULTS

It is interesting to note that almost every patient is immediately relieved of pain in the leg after the operative removal of the ruptured disk. In study of the end result evaluation of ability to work as well as of relief from pain was attempted. Eight cases are too recent to be included in the study of the end results. Of the remaining fifty patients, thirty-two are well. The

Fig 4—Normal filling of the lower lumbar subarachnoid spaces after the injection of 5 cc of iodized oil. The patient is in the upright position. Asymmetrical filling of the nerve sheaths is a normal variation.

have no pain and are able to engage in the activities they pursued before they were ill. Twelve additional patients are markedly improved but have some minor complaint, such as slight pain or sensation of weakness in the back, which prevents them from being rated as well. Two patients have had relapses and their operations are classed as failures. There was one post-operative death. Three other patients have died of incidental causes but were relieved of their pain during their postoperative life.

COMMENT

Certain points concerning the diagnosis and care in these cases need emphasis.

In our present state of knowledge we cannot yet make an accurate clinical diagnosis of ruptured intervertebral disk and must rely on roentgen studies after the subarachnoid injection of a contrast medium to verify clinical suspicions. Iodized oil should not be injected into the spinal canal of every patient suffering from "sciatica." Prolonged, adequate, conservative orthopedic care should be insisted on in every case of suspected rupture of an intervertebral disk before iodized oil is used. Injection of saline solution or procaine hydrochloride, manipulation and fasciotomy (Ober¹⁰) may be included as "conservative" measures

Fig 6—The rupture is unusually large and presents somewhat the appearance of an intradural tumor but its extradural position can be readily established by roentgenograms in the lateral view. The patient is in the upright position and there is complete filling above the lesion. Ruptured disk was found at operation.

If these fail to relieve the sciatica the diagnostic use of iodized oil is indicated before lumbosacral or sacroiliac fusion is resorted to, particularly if the total protein in the spinal fluid is elevated. The operation (laminectomy and spinal fusion) is a formidable one

and should not be advised except on the clearest indications and after the use of conservative measures have failed to give relief. The technic of examination with iodized oil is exacting, but in competent hands the accuracy of diagnosis is very high.

Localized arachnoiditis with matting together of the nerve roots has been found associated with ruptured

Fig 7—Filling defect produced by posterior rupture of the fifth lumbar disk. The sheaths of the first and second sacral roots are well filled on the side opposite the lesion. The defect is similar to but less definite than the defects seen at higher levels.

disk in at least three cases. We believe that it may have been caused by localized hemorrhage or trauma to roots and meninges at the time the disk was ruptured. In two cases in which ruptured disk was suspected,

the condition proved to be arachnoiditis without evidence of ruptured disk. It may be that the same sort of injury may cause either lesion or a combination of the two.

CONCLUSIONS

Rupture of a low lumbar intervertebral disk is one of the causes of severe intractable sciatic pain. The diagnosis can be made with a high degree of accuracy. The operation for removal of the extruded fragment

10 Ober, Frank R. Relation of the Fascia Lata to Conditions in the Lower Part of the Back. *J. A. M. A.* 109:554 (Aug. 21) 1937.

presents certain technical difficulties and is a procedure of some severity. The operative mortality is low. The percentage of cures is high.

ABSTRACT OF DISCUSSION

DR GEORGE I BAUMAN, Cleveland. Low back pain with or without "sciatica" is extremely common and easily diagnosed but its exact etiology is often veiled in deep mystery. The solution of this problem is facilitated by the method of exclusion: one excludes first the more common causes of such disability and only as a last resort subjects the patient to lumbar puncture and injection of iodized oil to discover an uncommon lesion of the intervertebral disk. Schmorl discovered a prolapse of the disk in 38 per cent of 3,000 spines examined at autopsy but rarely found a protrusion extending into the vertebral canal. Lesions of the disk, of the nucleus pulposus or even of the spine itself have been reported following a spinal puncture. The injection of iodized oil may result in untoward reactions, as suggested by the authors. A subsequent laminectomy may add to these possible hazards. To reduce this problem to its simplest terms and determine the approximate proportion of patients who might be benefited by this method of diagnosis and treatment, certain general rules might be laid down, always remembering that there are exceptions to all rules. 1. The nomenclature could be simplified. The authors have concluded that these are cases of neuritis. As "sciatica" does not cover the various lesions, the term "lumbosacral neuritis" is suggested. 2. Neuritis is usually due to absorption of some toxin most commonly from a focus of infection. Every such possible focus should be eliminated even to the extraction of a single nonvital tooth. After elimination of a focus of infection it may be necessary to wait several weeks for full benefit to show. 3. There remain a certain group of cases of neuritis due to pressure on a nerve root. This pressure may be within or outside the vertebral canal. The most likely point of pressure outside the canal is where the nerve root crosses the transverse process. In my experience many cases of intractable neuritis have been relieved by removal of the transverse process. The operation of transversectomy is devoid of many of the dangers of a laminectomy. The possibility of pressure of a transverse process or at the intervertebral foramen should be eliminated before one resorts to spinal puncture, injection of iodized oil or laminectomy. In the remaining cases there should be a clear history of trauma to justify the procedure. Even with such a careful sifting of cases there remain a certain number in which an accurate diagnosis can be made only by the technic described by Dr Barr and his associates. If then it is a proved case of intractable lumbosacral neuritis due to pressure by a herniated disk, a laminectomy is indicated and justified.

DR SAMUEL J LANG, Evanston, Ill. I should like to raise a few questions which must have occurred to those who have encountered these cases. The first question concerns patients having the clinical picture of unilateral sciatica and yet showing no visible disturbance of the disk on the x-ray film. That raises the question as to whether the annulus fibrosus can, in the absence of the nucleus pulposus, sustain the weight of the torso for any considerable time. Second, there arises the embarrassing experience which is best explained by the brief recitation of a case history. An intelligent business man sought relief from a severe unilateral sciatica and saddle area type of pain. For a period of three months he had walked with a shuffling gait because of the accompanying distress. He had been attended by several physicians, including myself, without relief. The x-ray films showed a complete flattening of the fifth lumbar disk. Surgical intervention was advised, but the patient was subsequently introduced to a gentleman in New York City, neither physician, osteopath nor chiropractor, who in three treatments provided complete relief. Three months has now elapsed without recurrence of symptoms. This type of response occurs with sufficient frequency to warrant investigation. It is my purpose to investigate this particular case.

DR F L REICHERT, San Francisco. In cases in which one places 5 cc of iodized oil in the spine and no operation is instituted because one does not find any intervertebral distur-

bance, the iodized oil remains in there. Some physicians have been hesitant about leaving that amount of so called innocuous material in the spinal canal. If there is any evidence of meningeal irritation, iodized oil has been found to produce further arachnoiditis. Before iodized oil became available there was air, and Dr Dandy for years has used air in the spinal canal so I resorted to the use of air and I can demonstrate the lesions with air just as readily as I can with iodized oil. When 10 or 15 cc of air has been used it is allowed to ascend into the cerebral subarachnoid spaces, where it is absorbed in ten or fifteen minutes, and that is the end of the story.

DR PHILIP LEWIN, Chicago. This is one of the most important papers that have come before our section and I think it is up to this group to try to put this matter on a definite basis. I would like to cite the case of a man who has been treated for a lumbosacral lesion. He has been examined by four recognized orthopedic surgeons in this room. He went to New York, where he saw a friend of his, a neurosurgeon, who said "This is the most typical case of prolapsed disk that I have seen this month. It should be operated on." The man returned to Chicago and saw one of the best neurologists in the city who said "If there is one thing I think it is not, it is an intervertebral disk lesion." I said "There are four men at a certain clinic I would like to have you see; all these men have written on this subject." After five days' examinations at a certain clinic, four especially interested men said "It is not a nucleus pulposus lesion." I am waiting for him to go back to New York and have his friend the neurosurgeon operate on him. One of the neurosurgeons in Chicago said to me "If I am ever found in a condition where I have to have excision of a nucleus I want the laminectomy, but I don't want an iodized oil injection showing what his opinion was of the injection of iodized oil. He would rather have the laminectomy as an exploratory procedure. I think it is important that within the next year or two these patients are going to be sent from pillar to post. They are losing their confidence in the doctors to whom they have been and too many of them are going to other places and too few of them will be relieved."

DR W J MINTER, Boston. There have been a good many questions raised concerning rupture of the intervertebral disk, and especially the question of the use of iodized oil. It has seemed to us that iodized oil is a substance which we would not use if we could help it, but in order to get the information that we wish both for the diagnosis and for accuracy of localization in order that we might operate on our patients with as little exposure as possible, we have used it and we have used it in practically every case in which we have operated. We have used iodized oil in this amount in about twenty cases in which no lesion was demonstrated by the use of iodized oil. Of those cases we have yet to see one in which any serious permanent lesion has occurred as a result of the use of iodized oil. There is no question that if we can find some other substance to substitute for iodized oil or if injection of air will give us equally good results, which with all due respect to Dr Reichert I rather doubt, we shall certainly give up the use of iodized oil. Until that time we shall keep on using it. Concerning the question of manipulation in these cases, treatment by osteopaths and so on, I think there is great danger of increasing the pain and increasing the disability. We have seen one or two cases in which marked damage occurred by sudden strain after symptoms had been present for a period of years. Operation should consist of a laminectomy of one lamina only in most instances with the lamina left long on one side the side opposite the lesion and wherever there is the slightest evidence of abnormal mobility in the spine we believe that a fusion operation of some sort should be combined with the laminectomy. I suppose that we have performed fusion operations in probably 40 or 50 per cent of the cases in which operation has been performed. Ruptured disk is one of the few causes of neuritis in the lower lumbar and upper sacral nerves in which a definite lesion can be demonstrated at operation. We have had a few negative explorations, but those negative explorations have been almost entirely in patients in whom a fusion was to be done if the exploration was negative. The exploration was an incident to a fusion operation which was carried out as soon as the laminectomy was finished.

CAUSATION BY TONIC SPASM OF THE LEVATOR
ANI, COCCYGEUS AND PIRIFORMIS MUSCLES
AND RELIEF BY MASSAGE OF THESE
MUSCLES

GEORGE H. THIELE, M.D.

KANSAS CITY, MO.

The efficacy of the treatment of coccygodynia is attested by the numerous forms of therapy which have been recommended. Results from rest, physical therapy and sedatives have not been satisfactory. Injections of various solutions into the soft tissues about the coccyx as recommended by Yeomans¹ and Kleckner² have been more encouraging. Too often coccygectomy has resulted only in chagrin for the surgeon and disappointment for the patient. Careful search of the literature appearing since 1859 fails to reveal a concept of coccygodynia which can harmonize the many forms of therapy which have been advised.

In a classic thesis published in 1859, Sir J. Y. Simpson³ called attention to the fact that, when the coccyx or the coccygeal joints had been injured or when the surrounding tissues were the seat of inflammation, any contraction of the muscles attached to the coccyx would excite the characteristic pain of coccygodynia. That statement is as true today as when Simpson made it and it is noteworthy that since his time although he has been quoted by scores of authors, not one has used this fundamental fact as the basis for a study of this crippling symptom.

Simpson did not mention muscle spasm which attracted my attention in 1934 when I first noted its association with coccygodynia. Continued observation since that time has confirmed the presence of tonic spasm of the levator ani and coccygeus muscles in my own twenty-eight cases of coccygodynia and in Wilson's⁴ series of eleven cases, which I have closely followed. Furthermore, it was early noted that a large percentage of patients with coccygodynia complained also of pain in the supragluteal region and/or down the back of the thigh and that in these patients tenderness and tonic spasm of the piriformis muscle were found almost without exception. Freiberg and Vinke,⁵ and Freiberg⁶ have published two excellent papers in which from an orthopedic point of view they discuss the relationship of piriformis spasm to sciatica.

In our thirty-nine cases of coccygodynia the pain was often so severe that a history of pain in the supragluteal region or down the back of the thigh was elicited only on questioning. In our other fourteen cases the complaint was of pain limited to the supragluteal region and/or down the back of the thigh.

CLINICAL MATERIAL

The clinical material used as the basis for this study consists of eighty-seven patients encountered in the practice of nine different proctologists. No patients with acute injury such as fracture or dislocation of the coccyx are included. The series consists of all the patients in these practices who complained of pain in the region of the coccyx in the supragluteal region or down the back of the thigh. For convenience the series is divided into two groups.

Group 1 consists of my own thirty-one cases extending back three years and of Wilson's series of twenty-two cases which began eighteen months ago. Group 2 is composed of the remaining thirty-four cases, which occurred during the past year in the practices of seven other proctologists in various cities of the United States. In the entire series there were thirteen males and seventy-four females. Their ages varied from 19 to 71 years with an average of 43.4 years. The duration of symptoms was from three days to thirty-

Fig. 1—Sagittal section showing the position of the finger during massage of the levator ani, coccygeus and piriformis muscles. The finger sweeps from side to side massaging lengthwise of the muscle fibers.

two years, with an average of about two years. Nineteen of the eighty-seven patients gave a history of trauma, which included falls, parturition and long automobile rides. The remaining sixty-eight cases may be placed in a large group classified by other writers as idiopathic. Several patients stated that their symptoms were first noted after a rectal operation. Three patients had had coccygectomies without relief. In thirty of the entire series of eighty-seven patients the pain was confined to the region of the coccyx, in seventeen it was confined to the supragluteal region or down the back of the thigh, and in the remaining forty coccygodynia was combined with pain either in the supragluteal region or down the back of the thigh.

CLINICAL HISTORIES

It is interesting to note that some of the patients stated that their pain first began as a sense of weight or heaviness which they at first referred to the rectum. This sensation gradually became more severe, and by

the time the patient sought relief he was complaining of severe aching or cramping pain referred to the region of the coccyx which was more noticeable when he was sitting in a hard chair, particularly when sitting was continued, or during the act of arising or sitting down. Inability to lie comfortably on the back was a frequent complaint, the pain being worse in that position. Lying on the side was preferred by the great majority. Periodic attacks of lancinating breath-taking coccygeal pain superimposed on the severe aching pain were frequent.

The pain down the back of the thigh varied from mild aching to the most severe boring aching pain during the presence of which the patient was unable to place the extremity in a comfortable position. There were frequent complaints of tenderness of the gluteus maximus close to its attachment to the coccyx.

Fig. 2—Anteroposterior view showing the position of the finger during massage of the levator ani, coccygeus and piriformis muscles. Note that only the finger tip reaches the piriformis muscle.

PHYSICAL EXAMINATION

As a class the patients walked somewhat stiffly and sat down cautiously, generally on one buttock and often close to the edge of the chair. On digital rectal examination with the patient in the Sims position spasm of the levator and the coccygeus is easily detected by lateroposterior pressure, the spastic muscles being felt stretched tightly from their origin at the arcus tendineus or ischial spine to the side of the coccyx and lower part of the sacrum. Coccygodynia was found to be accompanied by tonic spasm of the levator ani and/or coccygeus muscle in sixty-four of sixty-nine cases reported by nine different observers. Tenderness of these muscles was found in three of the remaining five cases.

The piriformis muscle is felt with the tip of the finger just distal to the sacrospinous ligament and lateral to the second, third and fourth sacral vertebrae (figs. 1 and 2). It is most easily felt on the right side when the

patient is lying on the left side and vice versa, and with one hand on the buttock one can often palpate bimanually.

Spasm of the piriformis is sometimes very difficult to ascertain with certainty, owing to the fact that the muscle is so far from the anus that its palpation is difficult. Shordania,⁸ in thirty-seven cases of piriformis in women with low backache, identified the muscle by its increasing size during external rotation of the extended thigh on the affected side. One can definitely state that many times the piriformis on the affected side feels firmer and offers more resistance to pressure with the finger than on the unaffected side. Freiberg's sign⁹ of piriformis spasm, as evidenced by limitation of motion in inward rotation of the fully extended thigh, is often positive. All the thirty-three patients with pain in the supragluteal region or down the back of the thigh seen by Wilson and myself had tenderness over the piriformis, and it was our opinion that thirty-one had piriformis spasm. Reports from seven other observers are incomplete in this respect and are therefore not quoted.

Tenderness of this group of muscles is unmistakable when present, the slightest pressure with the finger provoking cries of pain. Tenderness from digital pressure on the coccyx itself is not marked and may even be absent. The tenderness usually described as being present in the coccyx is in reality in the tissues just lateral to the bony structures. Movement of the sacro-coccygeal joint is most often productive of severe pain, but cases have been observed in which, although the joint could be moved painlessly, nevertheless the levator ani and the coccygeus muscles were extremely tender.

Supragluteal tenderness is present over the distribution of the superior gluteal nerve but is much more marked where the nerve emerges from between the piriformis muscle and the lower border of the gluteus medius (fig. 3).

Tenderness of the sciatic nerve is demonstrated in the usual manner by external pressure but is more pronounced when pressure on the nerve is made from within the pelvis.

I am not informed as to the remainder of the series, but, in Wilson's and my fifty-three cases of all types, orthopedic and gynecologic consultation and roentgenographic studies were freely used.

THE MODE OF PRODUCTION OF SYMPTOMS

After spasm was found in this group of muscles, an interpretation of the manner in which such spasm might have produced the symptoms observed seemed desirable. First of all one must remember that muscle spasm itself is very painful, and nothing further need be said to explain the pain in some of our cases of coccygodynia.

A full discussion of some of the mechanisms involved is contained in a former paper⁹ on this subject. Suffice it to say that spasm of both portions of the levator ani exerts forward as well as lateral traction on the coccyx. Unilateral contraction of the coccygeus exerts traction which is more nearly lateral. Thus it may be seen that in the presence of arthritis or trauma of the sacro-coccygeal articulation or the coccyx spasm of either or

⁸ Shordania, J. F. Die chronische Entzündung des Musculus piriformis—die Piriformitis—als eine der Ursachen von Kreuzschmerzen bei Frauen. *Med. Welt* 10: 999 (July) 1936.

⁹ Thiele, George H. Tonic Spasm of the Levator Ani, Coccygeus and Piriformis Muscles. Relation to Coccygodynia. *Tr. Am. Soc. Soc.* 37: 145, 1936.

these muscles would tend to increase the pain. It would seem that in such a case a vicious circle is established, i. e. pain, spasm, more pain and more spasm.

As has been stated, in patients who complained of pain in the supragluteal region and/or down the back of the thigh, the pelvic portion of the piriformis muscle on the affected side was more tender to pressure and its belly firmer to touch than on the unaffected side. This muscle arises from between the first four sacral foramina and also from the grooves leading from the foramina. A few fibers also arise from the anterior surface of the sacrotuberous ligament. If one considers the sacrum as the origin of the piriformis, then some of its lower fibers insert into the inferolateral margin of the great sacrosclatic foramen instead of arising there as stated in numerous textbooks on anatomy. This insertion into the inferolateral margin of the great foramen provides an efficient mechanism whereby contraction of the piriformis may squeeze the sciatic nerve against the lower border of the foramen formed by the sharp edge

of the sciatic nerve, particularly in the presence of a spastic coccygeus muscle and/or a shortened sacrospinous ligament. In a like manner it may also squeeze the superior gluteal nerve by pressure against the lower border of the gluteus medius.

In view of these factual and theoretical considerations it seemed desirable to determine whether or not such spasm of the levator ani, coccygeus and piriformis could be overcome by massaging these muscles with the finger through the rectum. Massage has been used by eight different proctologists in eighty of the eighty-seven cases reported in this study.

TECHNIC OF MASSAGE

Ely¹¹ in 1910 reported on the treatment of coccygodynia by massaging the coccyx and its immediate soft parts between the thumb and forefinger and stated that "usually two or three treatments at intervals of two or three days will suffice to cure." He did not mention muscle spasm nor did he describe massage of the levator ani or coccygeus muscles.

A uniform technic of massage has been used in all cases. With full length insertion of the finger in the rectum, lateroposterior pressure will place its flexor surface horizontally across the surfaces of the levator ani and coccygeus muscles almost at a right angle to their fibers (figs 1 and 2). The fibers of the piriformis are felt immediately beyond the sacrospinous ligament and are touched by the finger tip in such a manner that lateral motion of the finger will stroke lengthwise that portion of the belly of the muscle lying within the pelvis.

These muscles are massaged in the long direction of their fibers in the same manner that a strip is stroked by a razor. Massage is begun lightly. This is necessary because one does not wish to traumatize the extremely tender spastic muscles. The sacrospinous ligament is merely pressed on by the finger in a direction vertical to its long axis. As the patient makes subsequent visits, massage is made with increasing pressure. If a reaction evidenced by increased pain is evoked light massage is again reverted to and pressure is increased as tenderness decreases.

If definite improvement does not result after the first four to six massages over a period of a week or ten days orthopedic or other indicated consultation should be sought.

TABLE 1—Results of the Treatment of Eighty Patients with Spasm of the Pelvic Muscle Productive of Coccygodynia With or Without Pain in the Supragluteal Region and/or in the Thigh

of the sacrospinous ligament and the upper borders of the gemellus superior and coccygeus muscles (fig 3). In recent dissections I have noted that the lower border of the piriformis is somewhat sharp and tendinous in structure. This fact has also been noted by Freiberg¹⁰.

The piriformis passes out of the pelvis through the great sacrosclatic foramen and is inserted by a rounded tendon into the inner side of the upper border of the great trochanter. By its upper border this muscle is in apposition with the gluteus medius, from which it is separated by the gluteal vessels and the superior gluteal nerve (fig 3).

In the dissecting room the sciatic nerve was removed from the great sacrosclatic foramen. The index finger was then inserted into the space which had been occupied by the nerve, and the thigh was forcibly internally rotated while in extension. This maneuver tightened the piriformis and squeezed the finger between the lower border of the muscle above and the sacrospinous ligament forming the lower edge of the foramen below. Having made this observation one could not doubt that spasm of the piriformis could cause pressure on the

Fig 3—Posterior view of the hip showing the piriformis muscle as it emerges from within the pelvis through the great sacrosclatic foramen. Note that the sciatic nerve passes beneath the piriformis muscle whose lower fibers insert into the inferolateral margin of the great foramen. The superior gluteal nerve may be seen passing between the upper border of the piriformis and the lower border of the gluteus medius.

10 Freiberg, Albert H. (Cincinnati). Personal communication to the author.

RESULTS

The patients were given an average of eleven treatments over an average period of eleven weeks by eight different proctologists.

In my own series of thirty-one cases of coccygodynia with or without associated pain in the supragluteal region or down the back of the thigh, in which massage was the only therapeutic measure, nineteen patients (61.3 per cent) were cured, eleven (35.5 per cent) were definitely improved and one (3.2 per cent) was unimproved. Wilson, using the same technic in twenty-two cases, reported sixteen (72.7 per cent) cured, five (22.7 per cent) definitely improved and one (4.5 per cent) unimproved (table 1, group 1).

Mechling reported seven cases of coccygodynia in all of which he found spasm of the levator ani. All his patients were improved but none were cured. He did not use massage but depended on heat, rest, elimination forced fluids and occasional Turkish baths. The notable fact concerning Mechling's series is that he found levator spasm in all his cases.

Six other observers reported twenty-seven additional patients with spasm of the pelvic muscles and with

TABLE 2—Detailed Results in Fifty-Three Cases of Thiele and Wilson

Symptoms or Observations	No. of Cases	Cured	Improved	Unimproved
Pain and tenderness limited to coccygeal area	11	3 (45.5%)	3 (45.5%)	1 (9.0%)
Coccygodynia with or without hip and leg symptoms	39	23 (64.1%)	13 (33.3%)	1 (2.6%)
Pain in the thigh	78	27 (71.0%)	10 (26.3%)	1 (2.6%)
Supragluteal pain	32	23 (71.8%)	9 (28.1%)	0
Coccygeal tenderness	37	23 (62.2%)	12 (31.7%)	2 (6.0%)
Supragluteal tenderness	23	15 (65.2%)	8 (34.8%)	0
Tenderness of thigh	16	9 (56.2%)	7 (43.7%)	0
Tenderness of piriformis	42	28 (66.6%)	13 (31.0%)	1 (2.4%)
Tenderness and spasm of levator ani and coccygeus	44	28 (63.6%)	13 (34.1%)	1 (2.3%)
Spasm of piriformis	39	26 (66.6%)	12 (30.8%)	1 (2.6%)

symptoms similar to those of our group 1. These twenty-seven patients were all treated by massage. Of this group, thirteen (48 per cent) were cured, eleven (41 per cent) were definitely improved and three (11 per cent) were unimproved (table 1, group 2).

Combining the results of all observers, excluding those in Mechling's patients, who were not treated by massage, one finds that forty-eight (60 per cent) were cured, twenty-seven (33.7 per cent) were definitely improved and five (6.3 per cent) were unimproved.

Results of treatment by massage as regards the various symptoms and observations in Wilson's and my fifty-three cases (group 1) are shown in table 2.

SUMMARY AND CONCLUSIONS

Coccygodynia was found to be accompanied by spasm of the levator ani and/or coccygeus muscles in sixty-four of sixty-nine patients seen by nine different observers.

Spasm of the piriformis muscle was found in thirty-one of thirty-three patients with pain in the supragluteal region or down the back of the thigh (Thiele's and Wilson's).

There is a sound anatomic basis for the causation of coccygodynia by spasm of the levator ani and coccygeus muscles and for the production of supragluteal pain and pain down the back of the thigh by spasm of the piriformis muscle.

In the treatment of these complaints by massage of the pelvic muscles involved the technic outlined should be carefully followed.

In a series of eighty patients with coccygodynia or pain in the supragluteal region or down the back of the thigh who were treated by massage by eight different proctologists, 60 per cent were cured, 33.7 per cent were definitely improved and 6.3 per cent were unimproved.

ABSTRACT OF DISCUSSION

DR FERNANDO I. WILSON, Kansas City, Mo. I am indebted to Dr. Thiele for pointing out that some patients with coccygodynia and pain in the superior gluteal region with or without pain down the thighs may have spasms of such muscles as the levator ani, coccygeus and piriformis muscles or some combination of these three groups and that massage of this group of muscles will relieve pain in these areas. I have treated twenty-two cases by massage as described by Dr. Thiele. In eight of these cases, in addition to massage, an oil soluble anesthetic was injected into the spastic muscles. The latter procedure has now been discontinued not only on account of uncertainty and danger but because it was almost always necessary to continue the massage in order to give complete relief from pain. At the present time, if these patients have no pathologic condition of the anus I instruct them to pass a rectal dilator twice daily. This procedure will relax the sphincter muscles, and often the levator ani muscles will be likewise affected. The relaxation thus produced will render massage much easier and less painful. Considerable experience is necessary in order to estimate properly the amount of spasm present in one or more of this group of muscles or perform the massage properly. One eventually learns however, the proper amount of pressure to apply and also just where this pressure is most needed. Dr. Thiele has pointed out that spasm of muscles is in itself productive of most severe pain. He does not explain, however, the cause of spasm in this group of muscles. I have observed spasms of one or more of these muscles with its resulting pain in four types of cases: 1. Cases which followed an anal operation; 2. Cases in which there was anal disorder (fissure, cryptitis) and no disturbance of the sacro-iliac or lumbosacral joints; 3. Cases in which sacro-iliac or lumbosacral disease was present and no anal disorder; 4. Cases in which anal disease or disease of the lumbosacral or sacro-iliac joints was not present. In cases considered due primarily to anal disorder it is often advisable to relieve the spasm in one or more of this group of muscles under discussion by massage before removing the anal condition. This procedure will decrease postoperative distress and often eliminate high rectal pain which is often wrongly considered due to postoperative proctitis. I believe there are many patients who have pain in the lower abdominal quadrant due to spasm of the piriformis muscle on the affected side. Eight of the twenty-two patients in my series complained of pain in the lower abdominal quadrant. In every instance this pain followed the course of the iliohypogastric and the ilioinguinal nerve and could be exaggerated by pressure on the piriformis muscle near its origin on the affected side. Six of this group of eight cases have been relieved by massage of the piriformis muscle alone. The remaining two cases were cured by a combination of anal operation and massage.

DR EDWARD G. MARTIN, Detroit. I wish Dr. Thiele would elaborate on the technic of massage and particularly as to how long at each treatment also suggest how it is possible for this massage to relieve the symptoms permanently and often with so few treatments. In one of the two case records which I contributed there was a surprising and amusing experience. The man was athletic and played hand ball at the university club. He was referred to me after a urologist had excluded the urologic field as a factor. My examination was negative and with some hesitation I suggested that we might try massage of the piriformis muscle. One treatment was followed by two others at periods of four or five days then he stopped coming. After a month or two I mentioned this to the urologist who had referred him to me and suggested that probably I should not have given him these treatments. His reply was, 'He thinks you are marvelous, and the reason he has not returned is that he was entirely relieved of his pain.'

DR C. H. TERRELL, Richmond, Va. Dr Thiele read a paper along the same lines at the meeting of the American Proctologic Society at Kansas City last year. Since hearing his paper a year ago, I have seen eight patients with symptoms as described by him in whom definite contractions or spasms of the levator ani or of the piriformis muscles were found. In some cases both muscles seemed to be involved. These patients have been completely relieved or decidedly benefited by massage of these spastic muscles. I think Dr Thiele has not stressed enough the rectal pain often associated with spasms of these muscles. Most of my patients had considerable pain in the rectum which seemed to be more or less relieved following bowel movements. Many of them also suffered with low backache and in two women there were in addition complaints of painful sensations in one or both sides of the vagina. An interesting case in this series was that of a man who complained solely of pain in the rectum occurring most frequently in the middle of the night. Often he would be awakened by a sharp constant aching pain in the rectum which sometimes would last for several days. Examination disclosed that he had a decided spasm of the levator ani muscle on the left. Massage of this muscle would give him complete relief for several weeks. There have been a number of recurrences, however, but in each instance relief has been obtained by massage of the muscle.

DR GEORGE HENRY THIELE, Kansas City Mo. Dr Wilson mentioned the cause of pain. I am frank to confess I cannot answer that, but I believe that in the postoperative rectal cases the pain is due to a subconscious effort on the part of the patient to elevate the anus so it will not be hurt by the chair, and that in the subconscious act he probably subconsciously produces a spastic state of the levator ani muscle, which is productive of his pain. I feel sure that this is the proper explanation in one of my cases. Another cause may be rectal disease. I would say that possibly from 40 to 50 per cent of my patients had been operated on previous to the time I saw them, or that I operated on them, having been unable to get permanent relief by massage alone. Shordania of Germany states that piriformitis was found in 20 per cent of 450 cases of pelvic disease in women who complained of lower backache. I have seen several cases in which the pain appeared during pregnancy before the descent of the head into the pelvis, and I believe there must be a reflex there about which nothing is known at present. Dr Martin has asked about the duration of the massage. My cases were treated on an average of eleven times over an average period of eleven weeks. Each massage lasts not to exceed one or two minutes. Treatments are at first given every day or every other day, and the interval is lengthened as relief is obtained. Dr Terrell mentioned the fact that rectal pain with defecation is relieved by massage. I think that this relief can be explained by the fact that during active defecation the muscles relax and then contract to pull the anal canal up into normal position. Massage, by relieving the tonic spasm of the levatores ani, relieves the pain of the act of defecation. Vaginal pain is easily explained on the basis of levator ani spasm. I have seen several such cases. The night pain referred to is caused, I believe, by an acute cramp of the levator ani or coccygeus muscle. Such pain can often be duplicated in the office by making excessive pressure on the spastic muscles, and is stabbing or lancinating in character.

Antivivisection's Weakest Point—Herein it seems to me lies the weakest point in the opposition to experimentation on the basis of cruelty—namely that the animals whose preservation is desirable benefit from these investigations as greatly as man. There is no more notable example of this than the case of man's companion the dog. Through the deserved attachment which has grown out of this companionship a sentiment has arisen which would exempt the canine species from experimentation. But had such a law been put on the statutes, Copeman's discovery of the bacterial cause of distemper, and of a successful method of inoculation against this most fatal and distressing canine disease would have been impossible—Cushing, Harvey. *Consecratio Medici and Other Papers*, Boston Little Brown & Co 1928.

Clinical Notes, Suggestions and New Instruments

GONOCOCCIC SEPTICEMIA WITH PURPURA AND ARTHRITIS SUCCESSFULLY TREATED BY HYPERTHERMIA

ONIS GEORGE HAZEL, M.D. AND WILLIAM BENHAM SNOW, M.D.
NEW YORK

In a study of the literature we do not find a reported case in which gonococcic septicemia was successfully treated by hyperthermia. We feel that the reporting of any new and safe type of therapy in such a serious complication is warranted.

Many cases of gonococcic septicemia have been reported but relatively few have yielded positive blood cultures. The septicemia may be of very short duration and be followed by localization in a joint or joints or in a tendon sheath. The gonococcic septicemia that persists may or may not involve the endocardium. The prognosis of any case presenting endocarditis is not good. Thayer,¹ in an extensive autopsy study of endocarditis, found that 11 per cent of the cases were due to gonococci. Friedberg² has recently reported four cases of gonococcic septicemia that have come under his care. Three patients recovered without heart damage and the fourth suffered severe heart damage. All his patients gave positive blood cultures.

The actual reason why septicemia develops in some cases of gonorrhea and not in others is not well established. Some feel that instrumentation and self treatment are contributing causes. Some workers feel that the virulence of the organism and the resistance of the patient determine whether or not the infection will remain localized or become generalized.

Chart 1—Respiration pulse and temperature curves November 14 during first hyperthermia treatment (five and a half hours above 106 F)

Wheeler and Cornell³ have distinguished two types of gonococcic septicemia that which yields consistently positive and that which intermittently yields positive blood cultures. They feel that patients with endocarditis are more likely to yield consistently positive blood cultures.

The criteria for a diagnosis of gonococcic septicemia rests on the finding of a preexisting focus followed by chills, fever, leukocytosis and constitutional symptoms or by the more direct method of demonstrating the gonococcus in blood cultures. The presence of endocarditis may be evidenced by emboli in the artery of an extremity, in the lungs, brain, liver, spleen or kidney or on the sudden development and alteration of the heart murmurs.

The improved laboratory technic has contributed to the reporting of a larger number of cases of gonococcic septicemia in which there are positive blood cultures. The organism is not easily grown and one or two negative cultures should not be accepted as conclusive evidence against septicemia. Since chills and high fever always accompany this disease it is best to take cultures just before or after the peak temperature.

REPORT OF CASE

History—F C, a Puerto Rican, aged 40, admitted to the Presbyterian Hospital Oct 31, 1936, complained of fever, a skin rash, painful joints and a penile discharge. The discharge had developed five weeks before admission, one week after exposure. The daily temperature before admission had been between 101 and 104 F, with the peak coming in the afternoon. He had treated himself with potassium permanganate for two weeks. The joint pains were of two weeks' duration and the skin rash was of two or three weeks' duration.

Examination—The patient was chronically ill with a temperature of 100.8 F, pulse 110, respiration rate 20, and blood pressure 140 systolic, 92 diastolic. A generalized purpura was present, with the petechia more marked on the palms and soles. The ankles, knees, wrists and left shoulder were painful, but there was very little swelling. The heart showed a gallop rhythm and a soft precordial systolic murmur. The liver was one fingerbreadth below the costal margin and the spleen was two fingerbreadths below the costal margin. There was a slight urethral discharge but no tenderness or enlargement of the prostate.

Laboratory examinations revealed the following: Hemoglobin, 93 per cent, red blood cells, 5,200,000, white blood cells, 22,000, polymorphonuclears, 84 per cent, lymphocytes, 16 per cent, urine, 1 plus albumin, stool, negative. The Wassermann reaction was negative, prostatic and urethral smears were negative for gonococci.

Course and Treatment—Immediate blood cultures were taken and the patient was treated symptomatically for one week, during which time he had a daily temperature of between 100.5 F and 104.4 F. He was given codeine for pain.

One week after admission, the blood culture was reported positive for gram-negative diplococci, which were not agglutinated by meningitis serum. Since the purpura was of the

Chart 2—Respiration pulse and temperature curves November 23 during second hyperthermia treatment (five hours above 106 F)

type often seen with epidemic cerebrospinal meningitis, the medical service felt that antimeningococcus serum was indicated. He was given 30 cc intravenously without any change in his condition after seventy-two hours. Ten days after admission another culture was reported positive for gonococci. The organism gave all the fermentation tests for gonococci. Later, two more cultures were reported positive. November 14, fifteen days after admission, he was given five and one-half hours of hyperthermia, with a rectal temperature of from 106 F to 107.4 F. The hyperthermia was induced in a cabinet in which the heat transfer was made by using a fine vapor of warm water sprayed on the patient through atomizers at 50 pounds pressure. He was exhausted after the treatment and was given intravenous dextrose in saline solution. He felt that the treatment was so exhausting that he could not stand another. On the day following the treatment he had a chill and a temperature elevation to 105.6 F. The purpura had almost faded by this time and the joints felt less painful. A blood culture taken on the day after the first hyperthermia treatment was positive. During the next week he was very weak, and the temperature continued to be high except on alternate days, when it would not exceed 101 F. November 23 he was given a second hyperthermia treatment for five hours between 106 F and 107.8 F. He tolerated the treatment unusually well and said that he felt that he had been cured. The temperature returned to normal that evening and remained normal throughout the remainder of his hospital stay. The joint pain disappeared except for slight

pain in the left shoulder posteriorly and in the left arm, which has persisted. On the first day after his second treatment gonococci were found in the prostatic smears for the first time but when he was examined in the outpatient department three weeks later no organisms could be found in the prostatic smears.

SUMMARY

A case of gonococcal septicemia with purpura, arthritis and positive blood cultures was successfully treated by hyperthermia. 180 Fort Washington Avenue.

THE PHARMACOPEIA AND THE PHYSICIAN

THE USE OF CALCIUM AND THE CHOICE OF A CALCIUM SALT

JOSEPH C AUB, M D

BOSTON

This is one of a series of articles written by eminent authorities for the purpose of extending information concerning the official medicines. The twenty-four articles in this series have been planned and developed through the cooperation of the U S Pharmacopeial Committee of Revision and THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION—ED

PHYSIOLOGIC FACTORS

In order to understand the proper use of calcium in medication, it is essential to appreciate the exchange of calcium in the normal body. Most of the inorganic constituents of the body are not stored except in soft tissues but calcium is stored in vast quantities also in the bones. Bones may be divided physiologically into two parts: the cortex, which is essential for posture, which apparently metabolizes at a fairly constant level, and the fine bone trabeculae, which represent an available storehouse for retention or liberation of calcium salts.¹ In the field of inorganic salt metabolism this store is analogous to the retention of fat as a source of readily available calories. The exchange of calcium, therefore, is an open system with a large reserve reservoir. After absorption from the intestine, calcium may be promptly excreted or may be deposited, and excreted calcium may come from food or from this reservoir in the bones. Thus, in starvation or in simple calcium starvation the excretion is maintained at a relatively high level, which gradually depletes the bones. Partly as the result of this reserve, the calcium and phosphorus levels in the blood stream remain fairly constant in health and in most diseases, so that their routine determination but rarely gives an index of abnormality of calcium exchange.

There are several factors that influence the stream of calcium in the body.

Factors That Do Not Affect Normal Blood Levels—

1 With a diet inadequate in either calcium or phosphorus, a body storehouse of calcium would be gradually depleted, and this effect would be accentuated if the diet were one with an acid ash, for calcium is one of the lesser important mechanisms by which excess acids are neutralized in the body.

2 Excessive amounts of both thyroid and anterior pituitary secretion stimulate the calcium excretion to

¹ Bauer, Walter, Aub, J. C. and Albright, Fuller. *Studies of Calcium and Phosphorus Metabolism. V. A Study of the Bone Trabeculae as a Readily Available Reserve Supply of Calcium.* J. Exper. Med. 19: 145-161 (Jan.) 1929.

abnormally high levels. This is particularly true of thyroid extract and, in exophthalmic goiter, the calcium drain is far greater than even in hyperparathyroidism, in spite of the fact that normal blood levels are maintained. In hypothyroidism, the calcium excretion is below normal. With regard to tumors of the anterior pituitary gland, the calcium excretion is high in the urine in both acidophilic tumors and basophilic tumors. In all these conditions, marked osteoporosis and even pathologic fractures may occur.

Factors That May Affect Blood Levels—1 The secretion of the parathyroid glands has no influence on calcium absorption from the intestine but markedly influences the calcium and phosphorus levels in the blood stream. Deficient secretion is associated with a lower blood calcium and an elevated blood phosphorus and a diminished excretion of both in the urine. Because of this change in blood levels, tetany results. Excessive secretion raises the blood calcium, lowers the blood phosphorus and is associated with increased excretion of both of these in the urine. Much of this excretion may be derived from the bones unless very large amounts of calcium and phosphates are ingested. Because of the excessive urinary excretion, renal stones are apt to be produced.²

2 Vitamin D also influences the calcium stream. In therapeutic doses it may greatly facilitate absorption of calcium from the intestine and also the deposit of calcium phosphate in the bones. In excessive doses its action practically mimics that of parathyroid extract on the blood and excretion levels. In vitamin D deficiencies one gets the picture of infantile or adult rickets with its normal blood calcium and lowered blood phosphorus, and also the characteristic picture of rickets in the bones. According to Reed,³ calcium excretion may be increased without abnormal blood levels as a result of very large doses of vitamin D.

3 Vitamin C (cevitamic acid) also is a factor in calcium deposit in the bones, for its addition to a scorbutus-producing diet causes a rapid deposit of calcium at the epiphyseal ends of bones and in trabeculae.⁴

4 Steatorrhea, or Gee's disease, prevents the absorption of calcium because insoluble calcium soaps are formed in the intestine. As a result, osteomalacia may follow and become so marked that a low blood calcium may accompany the reduced blood phosphorus, with resulting tetany.⁵

5 Any tumor that has multiple metastases in bone may apparently cause an elevation of blood calcium with a normal blood phosphorus level. Multiple myelomas with their associated high total blood protein are apt to do this, but so are metastatic breast tumors and hypernephromas.

6 Severe chronic nephritis may also cause abnormalities in the blood with a low blood calcium and protein and a high blood phosphorus level.

TREATMENT OF CALCIUM ABNORMALITIES

It is obvious from the foregoing paragraphs that the use of calcium in therapy must be based primarily on a knowledge of the abnormality involved in this complicated metabolism. Blood analyses help considerably in this differential diagnosis. A prerequisite for successful therapy naturally rests in the correction of the fundamental abnormality.

Treatment to Increase Calcium Stores in the Bones—Whenever confronted with depletion of the calcium stores in bones, no matter what the cause, one should attempt to increase these stores by increased ingestion of calcium. This is best accomplished by the drinking of large quantities of milk, as the calcium in this food is readily absorbable. Roughly, a quart of milk contains a gram of calcium. If however, milk cannot be tolerated, other salts may be resorted to. Both calcium gluconate and calcium lactate are far more palatable and probably as readily absorbed as the salts of inorganic acids. However, because of the large molecules it requires 11.2 Gm of calcium gluconate and 7.7 Gm of calcium lactate to include 1 Gm of calcium. Under normal conditions from 0.5 to 1 Gm of calcium a day is certainly adequate for any person and 2 Gm of calcium will be considered a high daily intake. Whenever absorption of large quantities of calcium is desired, it is important that adequate intake of vitamin D also be maintained, as this facilitates the calcium absorption through the intestine.

Infantile rickets and adult osteomalacia may also be due to a deficient calcium intake, though the primary factor in this disease is usually a deficiency of vitamin D. It has recently been shown by Shohl⁶ that deficiency in either calcium or phosphate intake may also produce the characteristic picture of the disease. In childhood such a deficiency is usually in the phosphate ion, but in adults the phosphate intake is usually adequate, whereas the calcium intake may be deficient. In the treatment of this disease, therefore, the food deficiencies ought to be corrected and an adequate dose of vitamin D given. In severe cases a deposit of calcium phosphate in the bones may then be so rapid that tetany may supervene, and under these conditions the rapid administration of adequate calcium and phosphate is an essential part of therapy.

Treatment to Lower an Abnormally High Blood Calcium—When this is due to adenoma or hypertrophy, surgical removal of the excess parathyroid tissue should be resorted to. Postoperatively, one may then encounter tetany, which needs serious treatment. When it is due to excessive intake of vitamin D, one can only wait for the effect to wear off—which is a matter of several weeks. When it is due to metastatic neoplasm of the bones, irradiation is about all that is available.

Methods to Elevate a Low Blood Calcium—Methods to raise the blood calcium level and to increase calcium storage are essentially the same though therapy is pushed when the blood calcium must be raised. In severe tetany due to low blood calcium there may be very severe spasm of both striated and smooth muscle. To elevate the blood levels the need for calcium therapy may be so great that its intravenous use is essential as a life-saving measure. Under these conditions two salts of calcium may be utilized. Sterile calcium chloride may be given

intravenously in doses of 10 cc of a 5 per cent solution. It has several disadvantages, for occasionally thrombosis of the vein may follow its use, and if any of it is injected in the extravascular spaces a slough is apt to result and great pain is always experienced. Calcium gluconate, therefore, is a preferable preparation because it may be given without these disadvantages and may, indeed, be given intramuscularly. In doses of 10 cc of a 20 per cent solution it produces the characteristic calcium effect—a feeling of great heat suffusing the whole body, particularly noticeable in the mouth. The patient may also vomit. When these symptoms are obtained, administration of calcium intravenously ought to be stopped. Whenever a soluble calcium compound is given intravenously, the injection should always be made very slowly, preferably over a period of about five minutes, in order to obviate any possible effect on the heart. Such an injection should eliminate the signs of low calcium tetany. By the time an injection is over, there develops a dramatic relaxation of the intensive muscle spasm. This effect may last for as long as two hours. In the meantime a similar amount of solution of calcium gluconate may be injected intramuscularly, in order to prolong the effect. As injections of parathyroid extract have a latent period of four hours before exerting an influence on the blood calcium, this type of calcium gluconate injection may tide over a crucial period in the disease.

Calcium gluconate is of value also in other spasms of smooth muscle. Its effect is best observed in acute lead colic, in which morphine and other sedatives are not very efficient. An intravenous injection of solution of calcium gluconate or chloride will usually cause a prompt cessation of this pain, sometimes permanently, at other times for several hours. If it is necessary, a second similar intravenous injection may be given in two hours and probably in somewhat less time without deleterious effects. Intravenous administration of calcium compounds is of value also in the treatment of acute gallstone colic and renal colic, but it is to be expected that because of the mechanical obstruction in these conditions its effects will not be so dramatic as in lead colic.

Intramuscular Use of Calcium—The intramuscular use of the calcium salt appears to be indicated only in order to prolong the effects of intravenous therapy or for more rapid absorption than can be obtained through the gastro-intestinal tract. Calcium gluconate may be given in the same dosage as for intravenous therapy, but calcium chloride and similar compounds should never be so used because of their necrosing effect on the tissues.

Calcium by Mouth—The use of calcium compounds by mouth is naturally limited to more chronic conditions in which there is no urgency with regard to calcium absorption. Calcium when so given has but little influence on the normal blood calcium level, raising it in my experience not more than 1 mg., and that only temporarily. In patients with a low blood calcium, however, large amounts of calcium compound should be ingested for this increases the calcium stream in the body and has a more intense and prolonged effect on the blood level than in normal individuals. A high calcium diet can easily be obtained by means of milk, eggs and green vegetables. If calcium salts need to be added, they are most easily taken as chalk (calcium carbonate) or calcium gluconate or lactate. From 10 to 15 Gm a day may be given. Adequate doses of vitamin D should always be given to facilitate the absorption of calcium through the intestinal mucosa.

The Importance of Phosphates—Though this discussion is largely limited to calcium therapy, it must always be remembered that the metabolism of the calcium and phosphate ions is intimately interrelated. When the deficiency is dependent on inadequate phosphate, as sometimes occurs in childhood, an increased intake must be instituted. In adult life, with the heavy ingestion of meats, phosphate ingestion is usually adequate, but if this is not the case the deficiency should be corrected.

Parathyroid Extract and Vitamin D—These two drugs are aids in the control of calcium metabolism which should never be overlooked. The action of parathyroid extract was recently summarized in *The Journal* and therefore is not again discussed.⁸

Cod Liver Oil—The effects of overdosage of vitamin D also were discussed.⁹ In physiologic or pharmacologic doses, however, vitamin D is of great value in the absorption of calcium phosphate and in its deposit in the bones of growing children. It may be given in the usual pharmacologic doses, therefore, as *cod liver oil* or as *viosterol* in oil.

When viosterol in oil is used to raise the blood calcium, large amounts must be used (i.e., about 200,000 to 300,000 international units daily). Such large doses will gradually raise the blood calcium level. Regulation of the dose must be controlled by repeated blood calcium determinations, and levels above normal must be avoided as the elevated blood level remains for several weeks after viosterol is stopped. If toxic levels are reached, the anorexia, vomiting and languor are prolonged for about two weeks. The desirable level to maintain is a low normal blood calcium value of from 9 to 10 mg. per hundred cubic centimeters.

A satisfactory substitute for viosterol in oil is to be found in the fraction called dihydrotachysterol.

Vitamin C—As a deficiency of vitamin C has a marked effect on the deposition of bone, any difficulty with bone deposit should always be treated with an adequate vitamin C intake.

Thyroid—Thyroid is an excellent substance for increasing the rate of exchange of calcium salts. Certainly in hyperthyroidism there is a more rapid excretion of calcium than in any other known condition. This excretion is more nearly parallel to the extremely rapid circulation rate than it is to the basal metabolic rate, and it may be four or five times the normal amount. Thyroid, therefore, may be of considerable value in the treatment of tetany as well as in the treatment of ununited fractures, very likely because of its stimulating effect on the calcium metabolism of bone. This therapeutic effect in tetany described by Aub, Albright, Bauer and Rossmeisl¹⁰ has been denied by Freyberg, Grant and Robb¹¹ but reaffirmed by Cope and Donaldson.¹²

Other Uses for Calcium—There are conditions other than those already mentioned in which a high calcium intake is desirable. During pregnancy there is a large storing of calcium in the bones which is later utilized during the period of lactation.¹³ During lactation a positive calcium balance is usually not maintained, so that it is important to develop adequate calcium stores during the period of gestation, particularly the latter

half At this time it is desirable that a daily intake of 2 Gm of calcium be maintained It is highly likely that this plus viosterol would largely reduce the incidence of dental caries during the period of lactation¹¹ In childhood, during the growth both of the teeth and of the bones, a similar high calcium intake is needed and a daily ingestion of a quart of milk is then indicated¹²

The observations of Ann Minot indicate that a high calcium intake during acute liver damage is also of great therapeutic value as, in her observation, calcium was a life-saving measure in the liver damage that followed carbon tetrachloride poisoning in animals In this condition it is desirable to have the high concentration in the liver itself, and therefore giving it by mouth is indicated In severe conditions, however, when solution of dextrose is being given intravenously calcium gluconate can also be added to the intravenous therapy

As an Antacid—In the previous considerations, calcium has been given for the purpose of increasing the calcium stores in the body, but calcium may be used as an antacid¹³ by the giving of powdered calcium carbonate (up to 2 Gm) Because calcium is not absorbed as well as sodium in the gastro-intestinal tract and because of its ready deposit in bones, its use in large amounts is less apt to produce an alkalosis Its neutralizing effect with hydrochloric acid is analogous to that of sodium bicarbonate and the two salts are often given together for gastric ulcers A certain amount of this calcium is excreted by the kidneys, and when it is taken in conjunction with sodium bicarbonate, which is usually the case in ulcer therapy, this excessive calcium may be excreted in alkaline urine Under these conditions, in concentrated urine, calcium stones may be deposited in the urinary tract, and this complication should always be borne in mind as a possible sequel of its prolonged use as an antacid

When one wishes to produce an acidosis by means of chloride ions, as, for instance, preceding the use of one of the mercurial diuretics, calcium chloride may be used, because the chloride ion is much more readily absorbed than is the calcium ion¹⁴ As a result, calcium chloride will produce an acidosis, much like ingestion of large quantities of hydrochloric acid, but this reaction can be more readily obtained by the use of ammonium chloride, which is therefore now largely used for this purpose

Calcium has been used in the form of lime water to produce softer milk curds in feeding infants This has largely been discontinued because it necessitates using large amounts of lime water and because boiling and evaporation of milk accomplish a similar effect

There are other conditions in which calcium has been employed in which the physiologic indication is less clear but in which practical experience has indicated benefit Many dermatologists feel convinced that a high calcium intake is of benefit in eczema and similar diseases, though the physiologic reason for this is not clear When milk cannot be tolerated in these cases calcium gluconate or lactate by mouth may be tried as a therapeutic agent A similar situation exists in the treatment of allergic diseases

CONCLUSION

The use of calcium, therefore, in clinical medicine should usually be done in conjunction with the internal secretions and vitamins which influence its metabolism in the body Abnormalities of calcium metabolism are so often related to these accessories of calcium metabolism that no adequate therapy can be given without their adjustment and regulation

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH Secretary

PROPADRINE HYDROCHLORIDE—dl-phenyl-1-amino 2-propanol-1-hydrochloride—a hydro- α - β amino-propylbenzene hydrochloride— $C_6H_5CHOHCHNHCH_2HCl$ Propadrine hydrochloride is the monohydrochloride of a base resembling ephedrine (laevo- α -hydro- α - β -methyl-amino-propylbenzene) but differs in that the methyl group on the amino group is replaced by a hydrogen atom

Actions and Uses—Propadrine hydrochloride acts similarly to ephedrine When applied locally, in the form of a 1 per cent aqueous solution or 0.66 per cent jelly, it produces constriction of the capillaries, thereby shrinking the swollen mucous membranes It is said that its action is somewhat more prolonged than that of ephedrine It is also claimed that the anxiety complex is not so apt to ensue with propadrine hydrochloride as with ephedrine

Dosage—As a spray or instillation, 1 per cent aqueous solution or application of 0.66 per cent jelly locally, orally, as three-eighths grain capsule every two to four hours as indicated Although no toxic effects have been noted, continued overdosage should be avoided as with other vasoconstrictors

Propadrine hydrochloride occurs as a white crystalline powder possessing an odor resembling that of benzoic acid It is freely soluble in water and alcohol insoluble in ether chloroform and benzene Its aqueous solution is neutral to litmus Propadrine hydrochloride melts at 190-194 C

Dissolve about 0.5 Gm of propadrine hydrochloride in 25 cc of water and add 5 cc of a saturated solution of sodium carbonate. Cool in an ice bath and collect the resultant needle-shaped crystals on filter paper wash and dry at 80 C the melting point of the α -hydro- α - β amino-propylbenzene is 101-101.5 C

Dissolve 0.05 Gm of propadrine hydrochloride in 100 cc of water separate portions of 2 cc yield a yellow color with 5 drops of a 9 per cent ferric chloride solution (distinction from *cobefrin* *kephrine* *ephedrine*) no precipitate with potassium mercuric iodide solution (Mayer reagent) (distinction from *benzadrine*) To about 0.1 Gm of propadrine hydrochloride in 5 cc of water, add 1 cc of diluted hydrochloric acid and 1 cc of barium chloride solution no turbidity develops (sulfate)

Dry about 0.3 Gm of propadrine hydrochloride accurately weighed to constant weight at 100 C the loss in weight does not exceed 1 per cent Incinerate about 0.3 Gm of propadrine hydrochloride, accurately weighed the residue does not exceed 0.3 per cent Transfer about 0.2 Gm of propadrine hydrochloride accurately weighed to a 500 cc kjeldahl flask and determine the nitrogen content according to the method described in Methods of Analysis of the Association of Official Agricultural Chemists fourth edition page 23 art 19 the amount of nitrogen is not less than 7.34 per cent nor more than 7.52 per cent when calculated to the dried substance Transfer about 0.2 Gm of propadrine hydrochloride accurately weighed to a 400 cc beaker and determine the chloride content according to the method as described in Methods of Analysis fourth edition page 131 art 35 the amount of chloride found corresponds to not less than 18.85 per cent nor more than 19.95 per cent when calculated to the dried substance

Propadrin Hydrochloride-Sharp & Dohme—A brand of propadrine hydrochloride-N N R

Manufactured by Sharp & Dohme Inc Philadelphia and Baltimore U S patent 1989 093 (Jan 29 1935 expires 1952) Propadrine is a U S registered trademark but the firm disclaims any proprietary rights to the name

Propadrin Hydrochloride Capsules $\frac{3}{8}$ grain (0.074 Gm)

Propadrin Hydrochloride Nasal Jelly 0.66% Marketed in one-half ounce nasal tip collapsible tubes containing 0.66 per cent propadrine hydrochloride with sodium chloride menthol thymol and oil of lavender in a water soluble base chlorbutanol 0.5 per cent is added as preservative

Propadrin Hydrochloride Solution 1% An aqueous solution containing 1 per cent propadrine hydrochloride and 0.5 per cent chlorbutanol as preservative

THE AMERICAN FOUNDATION PROPOSALS FOR MEDICAL CARE

When the American Foundation Studies in Government obtained and published the views of numerous physicians concerning the present status and the future of medical practice, it was generally understood that conclusions would not be drawn and that a working program would not be proposed. The evidence was to be set forth with perhaps an analysis. Nevertheless, at the time of publication some earnest workers in the vineyard expressed the belief that certain deficiencies in the medical scheme were clearly apparent and that concrete proposals should be made which would have the approval of the medical profession and which might lead to governmental action. A conference was held in New York City. Later, as reported in the press, some of those present in the conference met with Mrs. Roosevelt and thereafter with the President of the United States. Still later a resolution from the House of Delegates of the New York State Medical Society, obviously a slightly modified form of the American Foundation proposals, was introduced in the House of Delegates of the American Medical Association at Atlantic City and there rejected with an enthusiastic unanimity which indicated quite clearly the utter dissatisfaction of the medical profession with these proposals. The proposals coming from the first conference (not the New York resolution) follow:

PRINCIPLES

- 1 That the health of the people is a direct concern of the government
- 2 That a national public health policy directed toward all groups of the population should be formulated
- 3 That the problem of economic need and the problem of providing adequate medical care are not identical and may require different approaches for their solution
- 4 That in the provision of adequate medical care for the population four agencies are concerned: voluntary agencies, local, state and federal governments

PROPOSALS

- 1 That the first necessary step toward the realization of the above principles is to minimize the risk of illness by prevention

2 That an immediate problem is provision of adequate medical care for the medically indigent, the cost to be met from public funds (local and/or state and/or federal)

3 That public funds should be made available for the support of medical education and for studies, investigations and procedures for raising the standards of medical practice. If this is not provided for, the provision of adequate medical care may prove impossible

4 That public funds should be available for medical research as essential for high standards of practice in both preventive and curative medicine

5 That public funds should be made available to hospitals that render service to the medically indigent and for laboratory and diagnostic and consultative services

6 That in allocation of public funds existing private institutions should be utilized to the largest possible extent and that they may receive support so long as their service is in consonance with the above principles

7 That public health services, federal, state and local, should be extended by evolutionary process

8 That the investigation and planning of the measures proposed and their ultimate direction should be assigned to experts

9 That the adequate administration and supervision of the health functions of the government, as implied in the above proposals, necessitates in our opinion a functional consolidation of all federal health and medical activities, preferably under a separate department

Since the annual session in Atlantic City in June, some of the members of the inner group, notably Dr. Hugh Cabot of Rochester, Minn., and Dr. Robert B. Osgood of Boston, have been circulating these principles among selected members of the American Medical Association with a view to obtaining their indorsement. Thus Dr. Hugh Cabot wrote to one physician in August:

Dear Doctor

A few of us who were included in the Executive Committee of the American Foundation for Studies in Government, whose Report has just appeared, are hopeful that certain basic opinions can properly be put forward based upon the weight of evidence in the Report. I think it important that a considerable group of influential and well-known physicians should assent to certain fairly general propositions, the tendency of which will be to show that what is needed is a very broad attack along a wide front rather than more narrow attacks upon limited objectives. There has, we think, been a good deal of rather just criticism of the medical profession on account of its unwillingness to advise positive rather than negative action. There seems to be some evidence that legislation looking toward compulsory health insurance has attracted a good deal of favorable attention in political bodies. It seems to us that compulsory insurance attacks only a very limited portion of the problem and that legislation to put this into operation might well do serious harm not because it would not be of assistance in solving certain problems but rather because it would help and might, therefore, tend to stop progress along a broader line.

Will you read over the enclosed statement of the Principles and Proposals and after due consideration, if you feel willing to approve, sign and return to me.

Sincerely yours
HUGH CABOT

Moreover, information comes to the effect that Dr. Robert B. Osgood at a recent meeting of the American Orthopedic Association requested many of those in attendance to sign these proposals and some did sign, one actually under the impression that these proposals represented an activity of the American Medical Association. Some orthopedic surgeons who signed have expressed indignation at the manner in which their

signatures were secured and have expressed now their opposition to governmental subsidy and control of medical practice

It should not be necessary to point out again in *THE JOURNAL* the danger of federal subsidies for medical schools and the hazard of turning over to the federal government the control and standardization of medical schools. Such subsidies may easily involve determination of the curriculum and administration of service through the medical schools which would quite certainly interfere with the advancement of medical education and medical science and put the government right into the practice of medicine. Already, in some foreign countries, the government controls the number of medical students and the nature of medical education. American medicine wants no such system. Our government has already voted \$750,000 a year for the control of cancer and suggestions have been offered that similar appropriations be made for the study of infantile paralysis, syphilis and other diseases. The danger of putting the government in the dominant position in relation to medical research is apparent.

Still more serious is the fifth proposal, to the effect that the government subsidize private hospitals in relationship to their laboratory, diagnostic and consultative services. The nonprofit voluntary hospital is the pride of American philanthropy and a major factor in maintaining a high quality of medical service. The tender of governmental funds to such institutions for the care of an ill defined group called the medically indigent appeals to the unthinking physicians who have endorsed these principles and proposals. Yet such an arrangement would put the hospitals promptly into the practice of medicine.

In a list of those who have already signed, submitted by the proponents with their request for additional signatures, there are now some 450 names. Space is not available nor does it seem desirable at this time to publish in *THE JOURNAL* the complete list of those who have signed. A cursory analysis of the list actually reveals the names of some physicians whose names are associated at the same time with views and actions opposed to those which they are here said to hold. Obviously some of these men must have signed merely after seeing the names of those who signed previously and because it looked like a "good" list. There appear also the names of some members of the House of Delegates which voted against some of the very propositions which these members here support. Most conspicuous on the list are the names of those deans and heads of departments in medical schools who may have signed because they saw a possibility of getting government money for clinics and dispensaries.

Such careless participation in propaganda as has here occurred is lamentable, to say the least. Certainly the unthinking endorsers of the American Foundation's principles and proposals owe to the medical profession some prompt disclaimers.

FACTORS INFLUENCING THE RETENTION OF IRON

The importance of an adequate supply of iron in the diet of man is well known. However, the total amount of iron in ingested foods is not the sole factor¹ in determining the amount of this element which is utilized by the organism. Of equal importance are the chemical nature of the compounds in which food iron is contained and variations in the absorption and retention of the substance under different physiologic and pathologic conditions. Prolonged diarrhea, for example, may lower the amount of iron absorbed and therefore the amount retained, presumably because of a decrease in the time during which the chyme is present in the intestine. The amount of hydrochloric acid present in the gastric juice likewise affects the absorption of iron. Patients with achlorhydria frequently have anemia of the iron-deficiency type. Indeed, it has been shown² that the decrease in gastric acidity following alkali therapy in cases of gastric ulcer may frequently be associated with an anemia amenable to therapy with iron.

Recently³ the influence of gastric acidity on the absorption and retention of iron has been studied by the "balance method" in patients with achlorhydria. They were fed an ordinary mixed diet supplying from 10 to 12 mg of iron daily. Patients with normal or only slightly low gastric acidity served as controls. Some of the latter were anemic. The results obtained showed convincingly that, as might be expected, patients with achlorhydria retained much less iron than did those with normal gastric acidity. Indeed, on the average, the achlorhydric patients excreted 4.4 mg of iron more than was ingested daily in the food, whereas those with normal gastric acidity excreted slightly less iron than that consumed in the food. The poorer retention of iron in the patients of the former group was undoubtedly correlated with the lack of hydrochloric acid in the gastric juice. These data also bring out clearly the fact that amounts of iron less than 12 mg daily are undoubtedly not sufficient to maintain a patient with achlorhydria in a state of iron equilibrium such as is the case with normal subjects.

It might be expected that the oral administration of hydrochloric acid to patients with achlorhydria might increase the absorption and retention of food iron. In further studies by the Iowa investigators, 200 cc of tenth normal hydrochloric acid was given three times daily with meals, no significant effect on the retention of iron was observed. These results appear to indicate that hydrochloric acid therapy in cases of achlorhydria is of little or no value as far as the absorption and utilization of food iron is concerned. The procedure of choice appears to be the administration of iron in the

form of one of its salts. Indeed, the investigators found that large amounts of iron, as iron ammonium citrate were absorbed and retained as well by patients with achlorhydria as by those whose gastric acidity was normal.

THE MISREPRESENTATIONS OF WILLIAM BRADY

In the education of the public about health and disease, Americans today have the benefit of advice from a considerable number of syndicated writers. No doubt the most widely circulated columns are those of Drs. James W. Barton, William Brady, Logan Clendenning, Royal S. Copeland, Irving Cutler, Morris Fishbein and Iago Galdston. Other columns with lesser circulation are written by Drs. Herman N. Bundesen, C. N. Chismen and J. J. Games, there are a half dozen more written by laymen and nurses, including a few dealing wholly with psychiatry. These columns vary in their instructive value and in their accuracy, as might well be expected. Most of them are quite certainly useful, particularly in causing patients to recognize promptly the serious character of some symptoms and to seek adequate medical advice. The column written by Dr. William Brady, once conspicuous because of its educational efforts, has during recent years gradually departed from anything resembling accuracy or established medical science. It seems to strive constantly for sensational effects. Hardly a week passes without a number of letters from people who have been confused by its pronouncements, requesting the facts, or from members of the medical profession protesting bitterly against its malevolent insinuations regarding the medical profession.

On September 20, a column by William Brady appeared in the Pontiac (Mich.) *Daily Press*, with the title "The New One-Shot Insulin." Shortly thereafter a prominent citizen of that city sent the column to the editor of a leading publication, with this statement:

If this is the truth, the medical profession, its universities and its ethical sponsors rate well down with Marijuana pedlers and below. If even part of his inferences should be true there is a vast overturning to be done here in the interest of the public and the freeing of the profession.

In this column, William Brady wrote:

Two factors have prevented many thousands of sufferers with diabetes from enjoying the boon of insulin treatment. First is the high cost of insulin which is artificially maintained under the monopoly granted to certain individuals or corporations by virtue of patents in the United States and Canada. This monopoly is sanctioned by the medical profession of both countries by some strange distortion of the fundamental principles of medical ethics.

This statement is absolutely untrue. Thirty units daily is about the average dose of insulin. The cost to the patient is usually less than 10 cents a day. When insulin was first discovered there was a period of approximately a year during which the cost was high, because manufacturers had to install large plants which

involved expenditures of many hundreds of thousands of dollars. Since that time the cost of insulin has been steadily reduced. None of the discoverers received one cent in royalty. A small payment is made to the Insulin Foundation, which, however, uses the money thus received to control definitely the quality of the material and to protect the public against contaminated or inefficient preparations.

Dr. Brady says in his next statement:

The second factor which has operated to withhold the benefit of insulin treatment from a great many diabetes patients is the onerous necessity of reporting two or three times a day to physician or nurse for the dose of insulin or even the task of preparing and administering the subcutaneous injection to oneself.

A physician whose practice is limited almost exclusively to diabetes and who is recognized throughout the world as a leader in this field makes the statement that he has not known or heard, during the past fifteen years, of ten physicians who give insulin daily to patients. Seldom are nurses required to make such injections and then it is only for patients who are helpless or who wish, because they are able to pay for such service, to have this attention. Moreover, the use of insulin has saved the lives of thousands of children who would quite certainly have died of diabetes if insulin had not been discovered.

Perhaps the most pernicious and false of all the insinuations in this item is the following:

Of course protamine insulin must be injected hypodermically like ordinary insulin. Scientific medicine, a field where humanity formerly had eminent domain, under the present monopolistic trend, is becoming subsidized medicine, and research or laboratory workers dependent on subsidies, grants, foundations or scholarships donated by commercial interests, discover what their owners want discovered or else. This unfortunate situation perhaps explains why we have not yet discovered a means of getting the effect of insulin from medicine the patient may take by mouth.

In research laboratories throughout the world ever since insulin was discovered, investigators have worked constantly and intensively to find some substitute for insulin that could be taken by mouth, in fact, such substitutes have been offered from time to time by investigators who felt that they had achieved this highly desirable discovery. Unfortunately, however, in each instance the preparation has been found by actual tests to be unreliable. A vast reward obviously awaits the independent nonmedical investigator, the manufacturer or the laboratory which makes this discovery. If, however, it is made by a physician, in accordance with the ethics of the medical profession, he will not derive any income in the shape of a royalty from his discovery.

The final paragraph of Dr. William Brady's article seems to be a promotion of vitamin B in the treatment of diabetes, arguing that patients with the disease have a lesser amount of sugar in their excretions when they take excess vitamin B for a few weeks, and stating also that patients with diabetes require less insulin when they take vitamin B. There is no good scientific evi-

dence to warrant this statement. If vitamin B were of any real value in diabetes, it would have replaced the use of insulin long ago because, like many other remedies, its attributed effect has certainly not been hidden under a bushel.

From time to time in the past, THE JOURNAL has called attention to other errors and idiosyncrasies in the writings of Dr. William Brady. The notions therein expressed regarding infection, the weird ideas of physiology, the preposterous slang, and the pseudo-humor, all coupled with false and unwarranted insinuations regarding medical service, have made Dr. Brady's column of late an unsound guide for any reader.

Current Comment

"MUCIN VIRULENCE" OF HAEMOPHILUS INFLUENZAE

The possibility of increasing the virulence of pneumococci, streptococci, staphylococci or meningococci by suspending these bacteria in 5 per cent gastric mucin was discovered about five years ago by Nungester and his associates¹. Their observations have been confirmed by other investigators². Recently Fothergill and his co-workers³ at the department of bacteriology of Harvard Medical School have applied the Nungester technic to a restudy of the toxicity and pathogenicity of the influenza bacillus. They found that it was necessary to inject a 1:4 dilution of a standard suspension of *Haemophilus influenzae* intraperitoneally into mice to cause death. The same micro-organisms suspended in 5 per cent gastric mucin, however, would kill mice if injected in dilutions as high as 1:40,000. The micro-organisms thus injected rapidly invade the blood stream, about twenty-five micro-organisms (plate count) per drop of tail blood being demonstrable by the end of fifteen minutes, increasing to many thousand bacteria per drop by the end of forty-five minutes. As soon as possible after death, one drop of heart blood (or a small quantity of peritoneal washings) was mixed with 1 cc. of 5 per cent gastric mucin and injected intraperitoneally into a second normal mouse. In this way as many as eleven successive mouse passages were made before the series was interrupted by contamination. After ten passages the "mucin virulence," i. e., virulence of the micro-organisms when suspended in 5 per cent gastric mucin, was increased a hundredfold. There was, however, no demonstrable increase in the toxicity or pathogenicity of the culture when injected without admixture with mucin. Whether the increased virulence caused by suspending *Haemophilus influenzae* in commercially available gastric mucin has any bearing on the problem of the infectivity of the influenza bacillus through the nasal or gastric mucosa has not yet been determined.

INHERITANCE OF PARALYSIS AGITANS

Although many causes have been suggested for Parkinson's disease, one of recurring interest is the factor of heredity. Allan¹ examined seventy-two consecutive patients with the shaking palsy from whom it was possible to secure an adequate family history. In seven there was no family history of the disorder but a past history of probable encephalitis, in twenty neither the family nor the past history offered an explanation, but in forty-five cases near relatives, parents, siblings or children had the same disorder. From twenty-four patients it was possible to obtain rather complete family history, and charts showing the pedigrees were reproduced. There were seventy-nine instances in which the trait was present in the children and in one parent. In thirty-six cases palsy was present in the parent but not in the children, but in twenty-eight of these families the children were under 50 years of age. In eight a generation was skipped, and in six a whole sibship was reported as having palsy. In three instances both parents had palsy. In one instance there were six children under 40, with one affected. In another family all four children lived to be over 70 and were affected, and in one all four children from 27 to 33 years of age were said to be affected. Although some of the facts of this investigation in North Carolina suggest the recessive character of this trait, the weight of evidence indicates that, in about two thirds of the cases studied, paralysis agitans was inherited as a dominant trait, probably conditioned by a single autosomal gene.

PECTIN AS AN ANTISEPTIC

The tentative use of pectin-agar-maltose mixtures in the treatment of diarrheas of infants led Edith Haynes¹ and her associates at the Indiana University Medical Center to study the possible bactericidal action of commercially available pectins. They found that 2 per cent commercial pectin added to heart-infusion broth would kill *Escherichia coli* within twenty-four hours, while control cultures adjusted to the same pH showed a thousandfold increase in bacterial count. This in vitro bactericidal property, however, is dependent on the acidity of the pectin broth mixture. The antiseptic properties are completely inhibited by adjusting the reaction of the mediums to neutrality or alkalinity. While pectin, therefore, might be expected to be an effective antiseptic in the stomach, it would be expected to be ineffective in the normally alkaline intestinal tract. Aqueous solutions of pectin are apparently nonirritating when applied to exposed wound surfaces. When applied to infected wounds, pectin causes a marked decrease or complete disappearance of local streptococci and staphylococci. Its application also appears to stimulate the growth of granulation tissues. These observations would seem to warrant a further study of pectin as a surgical dressing.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES NEW HOSPITALS EDUCATION AND PUBLIC HEALTH)

CALIFORNIA

University News—A new department of public health nursing has been announced at the University of California at Los Angeles, with Eleanor L. Beebe in charge as assistant professor of public health nursing.

Annual Symposium on Heart Disease—The heart committee of the San Francisco County Medical Society will hold its eighth annual graduate symposium on heart disease at the University of California, Stanford University and San Francisco hospitals, November 17-18. The course will cover the various aspects of heart disease, including diagnosis, prognosis and treatment. Recent advances in cardiology will be reviewed and evaluated and practical clinical demonstrations will be held. The registration fee will be \$2.

Society News—Dr. Victor G. Heiser, New York, lectured at the Philharmonic Auditorium, Los Angeles, October 11, under the auspices of the Modern Forum, on "More of an American Doctor's Odyssey."—Dr. Dean E. Godwin, Long Beach, among other speakers, will discuss two cases of Streptococcus haemolyticus meningitis with recovery following use of sulfanilamide before a joint meeting of the Los Angeles Society of Ophthalmology and Otolaryngology and the Research Study Club of Los Angeles, October 18.—The Los Angeles Obstetrical and Gynecological Society was addressed, October 12, by Drs. Francis M. McKeever and Harry Dietrich on "Late Results of Birth Injuries" and "Early Recognition and Treatment of Birth Injuries" respectively.—Dr. Ludwig A. Emge, San Francisco, discussed "Treatment of Pelvic Cancer in the Female" before the San Diego County Medical Society, October 12.

CONNECTICUT

Personal—Dr. Mario L. Palmieri has been appointed health officer of Middletown on a full time basis, and Dr. Homer C. Ashley has been appointed to a similar position in the town of New Hartford, succeeding Dr. Theodore B. Ackerley.

Health Field Day—Health agencies of the town of Greenwich sponsored a "health field day" September 15 with general sessions in the morning and evening and section sessions in the afternoon. Speakers included:

Dr. Matthias Nicoll Jr. White Plains N. Y. Unsolved Problems in Public Health
Ira V. Hiscock CPH New Haven Conn. The Twenty Points on Which Health Conservation Contests Are Based
Roger L. Offen DDS Stamford Dental Caries
Dr. Charles A. McKendree New York Neuropsychiatric Trends in Economic Depressions

DISTRICT OF COLUMBIA

New Brain Research Institute—The Georgetown University Brain Research Institute was established at the university's school of medicine, September 10, under the direction of Dr. Othmar C. Solnitzky, professor of anatomy, with Dr. Francis J. Warner as assistant director. A program of neurologic research will be launched along the following directions:

1. A complete study of the brains of vertebrates from the cyclostomes to the primates.
2. A thorough study of the development of the human brain with special regard to its morphology, nuclear masses and fiber tracts.
3. Experimental study of the function of the various nuclei and fiber tracts of the brain by means of Marchi degeneration and retrograde cell degeneration.
4. A comprehensive study of the neuropathology of the human brain.

The institute already possesses a large collection of animal and human brains, many of which are sectioned and stained and an animal experimental laboratory is being built. A large library of books, monographs and reprints covering every phase of the projected research is available. All the facilities of the institute will be made available to those interested in any phase of brain research. Individual desks and microscopes will be placed at the disposal of investigators. Contributions of animal and human brains, both normal and pathologic as well as reprints of all neurologic publications will be gratefully accepted and duly accredited it was announced.

FLORIDA

District Meeting—The first annual meeting of the South Central Medical District of the Florida Medical Association will be held at Melbourne, October 21, at the Golf and Country Club. The speakers will include Drs. Charles J. Collins, Orlando, on "Abnormal Bleeding in the Middle-Aged Woman," Ernest W. Potthoff, Titusville, "Common Skin Diseases in General Practice," and Eugene L. Jewett, Orlando, "Bone Injuries in General Practice."

ILLINOIS

Society News—Dr. Herbert N. Rafferty, Robinson, read a paper entitled "Success in Hernia Repair" before the Willamson County Medical Society at Marion, October 7.—The Will-Grundy County Medical Society was addressed at Joliet, October 6, by Dr. George de Tarnowsky, Chicago, on gall bladder disease.—The Physicians' Association of the Illinois Department of Public Welfare will hold its second annual meeting in the rooms of the Kankakee Medical Society, Kankakee, October 22, under the presidency of Dr. George A. Wiltrakis, Elgin. Speakers will include Drs. Shirley W. Lane, Kankakee, on "Medical Economics in Relation to State Service," Louis Belinson, Lincoln, "Progressive Muscular Dystrophy," and G. Heilbrunn, Elgin, "Insulin Shock Therapy in Dementia Praecox."

Chicago

University News—The speakers at the banquet session of the symposium on occupational diseases of Northwestern University Medical School, September 28 were Mr. B. C. Heacock, president, Caterpillar Tractor Company, Peoria, and of the Illinois Manufacturers Association, on "The Prevention of Occupational Disease," and Dr. Morris Fishbein, Editor, THE JOURNAL, "The Future of Industrial Medicine." Dr. Irving S. Cutter, dean of the medical school, was toastmaster.

INDIANA

State Medical Election—Dr. Edmund M. Van Buskirk, Fort Wayne, was chosen president-elect of the Indiana State Medical Association at its annual meeting in French Lick, October 6. Dr. Herman M. Baker, Evansville, will become president January 1, succeeding Dr. Edmund D. Clark, Indianapolis. The association will hold its next annual session in Indianapolis in 1938.

Society News—Dr. Fred R. Clapp, South Bend, discussed leukorrhea before the St. Joseph County Medical Society in South Bend, September 14.—At a meeting of the Fort Wayne Medical Society, Fort Wayne, September 14, Dr. Jerome R. Head, Chicago, discussed thoracic surgery.—Dr. John deJ. Pemberton, Rochester, Minn., addressed the Tippecanoe County Medical Society, Lafayette, September 14, on "Carcinoma of the Rectum and Rectosigmoid."

Sources of Infection Traced in Syphilis Campaign—An effort is being made to trace all sources of infection in the new patients with syphilis who this year entered the clinic of the Indianapolis City Hospital, Indianapolis, as a part of the local campaign against the disease. A preliminary step in the campaign included a study of the age, race and occupation of these patients with a view to drawing up a plan to control the disease. The council of the Indianapolis Medical Society has approved the program, which depends largely on the independent practitioners' cooperation with local health authorities. One objective of the campaign is "no child born with syphilis in Indianapolis by 1940!"

IOWA

District Meeting—The Iowa-Illinois District Medical Society met in Davenport, September 29, when the following program was offered:

Dr. Fredrick A. Wilhus Rochester Minn. Coronary Disease
Rev. Alphonse M. Schwitalla SJ St. Louis Social Aspects of Medical Practice
Dr. George de Tarnowsky Chicago Lon Back Pain
Dr. Morris Fishbein Chicago Social Security and the Doctor

Interns Hold Graduate Conference—About 150 former interns of the Iowa Methodist Hospital, Des Moines, members of the current class, members of the hospital staff and several guests attended a breakfast, August 22 after which the following speakers among others participated in a graduate conference: Dr. Thomas A. Burcham Des Moines Cholecystography, Dr. Howard I. Down Sioux City, Carcinoma of the Rectum, and Dr. Samuel J. Lang, Evanston, Ill., 'Loa Back Pain'.

LOUISIANA

Personal—Dr Murphy M Sims, Benton, has resigned as health director of Bossier Parish to engage in private practice, Dr Herbert N Barnett, New Orleans, has been appointed acting director

Prohibit Sale of Proprietary Drugs for Weight Reduction—The sale of proprietary drugs for reduction of body weight is prohibited by law in Louisiana, in accordance with a regulation adopted by the Louisiana State Board of Health, September 15. Manufacturers and dealers are warned that this regulation will be rigidly enforced in the interest of the protection of the public health

MARYLAND

New District Health Officer—Dr Charles Howe Eller, Richmond, director of the bureau of rural health, Virginia State Department of Health, has been appointed health officer of the Eastern Health District in Baltimore, effective October 1. He succeeds Dr Harry S Mustard, who resigned to become the Hermann M Biggs professor of preventive medicine, New York University College of Medicine, New York. According to *Baltimore Health News*, the choice was announced by the Johns Hopkins School of Hygiene and Public Health, which has established a special area for teaching and research in the district. A graduate of the University of Colorado School of Medicine, Denver, Dr Eller has served as health officer of Valencia County, N M., and as health officer of Charlottesville, Va.

Spotted Fever and Psittacosis Made Reportable—Rocky Mountain spotted fever and psittacosis have been added to the list of reportable diseases in Maryland according to a recent announcement from the state board of health. The complete list now includes typhoid, undulant fever, tularemia, malaria and typhus fever, the so-called children's diseases, including whooping cough, scarlet fever, diphtheria, measles and infantile paralysis, diarrhea, dysentery, influenza, septic sore throat, the pneumonias, tuberculosis, smallpox, trichinosis, syphilis, gonorrhea and other infectious or contagious diseases. Certain diseases, such as tetanus, and diseases that may be contracted in certain occupations, such as lead poisoning and certain forms of skin diseases, are also reportable, the department stated.

MICHIGAN

Personal—Dr Emily L Rikpa has been appointed field physician for the bureau of child hygiene and public health nursing of the state department of health, succeeding Dr Vida Gordon, who resigned to accept a position with the University of Michigan Health Service. Dr Berneta Block, Pyengyang, Korea, has been appointed field physician, succeeding Dr Pearl A Tononen, resigned.—Dr Hugo A Freund, Detroit, has been appointed a member of the Public Welfare Commission of Detroit.—Dr Roy D McClure, Detroit, read a paper entitled "The Tannic Acid Treatment of Burns" before the forty-sixth session of the French Congress of Surgery in Paris, October 4.—Dr John E Handy, Caro, was guest of honor at a dinner in Caro, October 7, given by the Tuscola County Medical Society in recognition of his completion of fifty years in the practice of medicine.

MINNESOTA

Graduate Courses—Clinics, lectures and demonstrations make up the graduate courses now being offered at the Center for Continuation Study of the University of Minnesota, Minneapolis, in cooperation with the Minnesota State Medical Association. *THE JOURNAL* reported the first of these institutes September 18, page 962. Others in the series include the following:

Surgical Diagnosis and Treatment November 16
Dermatology and Syphilology December 6-11
Ophthalmology and Otolaryngology January 16-21
Medical Diagnosis and Treatment February 7-12
Traumatic Surgery March 7-12
Endocrinology April 4-9

The dates for the remaining courses in diagnostic radiology, clinical pathology and proctology have not been definitely determined. Each seminar will occupy the full time of those taking the course from Monday to Saturday inclusive. There will be no evening classes. Special library facilities for each seminar will be provided at the center which also offers living accommodations. Round table conferences are held at the close of the daily program to give the graduates an opportunity to ask questions. All correspondence should be addressed to the director of the Center for Continuation Study, University of Minnesota, Minneapolis or Dr William A O'Brien, medical representative at the same address.

MISSOURI

New Cancer Commission—Appointment of the full commission to select a site for, construct and operate a state hospital for indigent cancer patients has been announced. Dr Ellis Fischel, associate professor of surgery, St Louis University School of Medicine was appointed chairman of the commission several months ago. Other members are Dr Paul F Cole, Springfield, Ed F Swinney, banker of Kansas City, and Waldo Holt, Louisiana, president of the Missouri Bankers Association in 1931.

Dr Eaton Goes to Rockefeller Foundation—Dr Monroe D Eaton Jr of the department of bacteriology and immunology, Washington University School of Medicine, St Louis, has been appointed to the staff of the International Health Division, Rockefeller Foundation, New York, effective September 1. His work in the laboratories of the health division at the Rockefeller Institute is concerned chiefly with studies of malaria. Dr Eaton graduated from Harvard University Medical School, Boston, in 1930.

Clinical Pathologic Conferences—Nine clinical pathologic conferences will be held by the Jackson County Medical Society during its coming program year. With emphasis on the clinical aspect, an attempt will be made in every instance to correlate the relationship of symptoms and signs to the lesions observed. The first conference was held September 28, when three cases of sudden death from heart disease without gross changes and a case showing a mediastinal condition were presented. At its regular meeting, September 21, Dr Arthur E Hertzler, Halstead, Kan., discussed "Operating Room Diagnosis of Breast Tumors."

MONTANA

Plague Infection—*Public Health Reports* states that plague infection was reported, under date of September 2, to have been demonstrated, by animal inoculation, in tissue from two ground squirrels (*Citellus elegans*) taken separately, August 20 and 23, 4½ and 5 miles southeast of Cameron, Madison County.

NEBRASKA

Mid-West Clinical Assembly—The Omaha Mid-West Clinical Society will hold its fifth annual assembly at the Hotel Paxton, October 17-22, under the presidency of Dr George A Young. The program will include:

Dr Hans H F Reese, Madison, Wis. The Constitution and the Biochemical Evaluation of the Nervous Patient
Dr Owen H Wangenstein, Minneapolis. The Significance of Mechanical Factors in the Genesis of Acute Appendicitis
Dr William J Kerr, San Francisco. The Anxiety States in General Practice
Dr Luther Emmett Holt Jr, Baltimore. Abnormalities of Fat Metabolism in Childhood
Dr Thomas Leon Howard, Denver. The Present Status of Urinary Bactericides
Dr Willis D Gatch, Indianapolis. The Recognition and Treatment of Bowel Obstruction
Dr William L Benedict, Rochester, Minn. External Diseases of the Eye in Relation to General Systemic Diseases
Dr Jesse L Bollman, Rochester, Minn. The Experimentally Produced Peptic Ulcer: Development and Treatment
Dr Edward A Schumann, Philadelphia. Observations on Ectopic Pregnancy
Dr Arthur Bruce Gill, Philadelphia. Treatment of Arthritis from the Orthopedic Point of View

There will be daily round table luncheons and informal dinners in the evening. A public meeting will be addressed Sunday evening, October 17, by Dr Thomas Parran, surgeon general U S Public Health Service, Washington, D C., on "Syphilis and the Public Health." Wednesday evening, October 20, has been designated "Omaha-Douglas County Medical Society Night."

NEW YORK

Hospital News—Two orthopedic services at the Rochester General Hospital have recently been combined with Dr Edward T Wentworth as chief of the service.—A new three story addition to St Joseph Hospital Far Rockaway was dedicated recently, giving the hospital a capacity of 135 beds.

Personal—Dr Clifford R Hervey, Oswego, retired August 31 after twenty years in the health service of the state, he joined the state department of health as sanitary supervisor in 1917 and received the title of district state health officer in 1923.—Dr Charles H Cole, for sixteen years superintendent of the Tuberculosis Hospital of Broome County, Chenango Bridge, retired from active service September 30.

Society News—Dr Russell L Cecil, New York, discussed "Serum Treatment of Pneumonia" before the Medical Society of the County of Nassau, Mineola, September 28, Dr Theo-

dore J. Curphey, New York, "Bacteriology of Pneumonia and the Modern Method of Typing," and Dr. Edward S. Rogers, Albany, "The State Campaign Against Pneumonia"—Dr. Walter T. Dannreuther, New York, addressed the Dutchess County Medical Society, September 8, on "Uterine Displacements."

Clinical Meeting of Buffalo Academy—The Buffalo Academy of Medicine will hold a clinical session at the Hotel Statler, Buffalo, November 17, with the following speakers:

Dr. Rudolf Schindler, Chicago. Clinical Value of Gastroscopy.
Dr. Robert L. Levy, New York. The Use of Drugs in the Treatment of Heart Disease.
Dr. Irvin Abell, Louisville, Ky. President American Medical Association. Responsibility of the Profession.
Dr. Richard B. Cattell, Boston. Diagnosis and Management of Surgical Diseases of the Colon and Rectum.

Dr. Morris Fishbein, Chicago, Editor, *THE JOURNAL*, will speak at the dinner on "Social Security and the Physician."

New York City

First Harvey Lecture—Selig Hecht, Ph.D., professor of biophysics, Columbia University, will deliver the first Harvey Society Lecture of the current series at the New York Academy of Medicine, October 21. His subject will be "The Nature of the Visual Process."

Unnecessary Noise Reduced—Figures recently released by Dr. John L. Rice, the city health commissioner, indicate that the ordinance on noise abatement in New York has been effective. From April 21, 1936, when the ordinance was enacted, until Jan. 1, 1937, the city health department handled more than 900 complaints. From Jan. 1, 1937, to October 5, the department handled about 200 complaints made directly to it and an additional 434 referred by the mayor's office. A review of the campaign against noise shows the result of a concentrated attack on the problem. In 1929, the appointment of a noise commission was announced and the facilities of the health department were placed at the disposal of the commission which embarked on a three-year study of noise. The Noise Abatement Commission was dissolved in 1932, and a second report was published in the fall of that year outlining methods by which the commission believed a municipality may achieve reasonable quiet. The city ordinance has already shown evidence of beneficial results.

NORTH CAROLINA

Hospital News—Dr. Joseph R. Blalock, New York, conducted a two-week psychiatric clinic at the State Hospital, Raleigh, August 1-14.—The name of the Sternberger Children's Hospital, Greensboro, has been changed to the Sternberger Hospital for Women and Children.

Society News—Dr. Lewie M. Griffith, Asheville, addressed the Buncombe County Medical Society, September 20, on "Four Hundred and Four Cases of Maxillary Sinusitis, a Clinical Analysis" and Dr. John L. Ward, Asheville, reported a case of Rocky Mountain spotted fever.—Drs. Gilbert M. Billings, Morganton, and Henry Eugene Barnes Jr., Hickory, addressed the Catawba Valley Medical Society, September 14, on "Plastic Surgery of the Nose" and "Some Aspects of Gonorrheal Therapy" respectively.

Personal—Dr. Isaac E. Harris Jr., Creedmoor, has been appointed to the staff of a hospital on the plantation of the Firestone Tire and Rubber Company in Liberia, according to a newspaper report.—Dr. Samuel M. Bittinger, assistant superintendent and associate medical director of the North Carolina Sanatorium for the Treatment of Tuberculosis, has been chosen assistant superintendent and medical director of the state's new sanatorium soon to be opened on Black Mountain, it is reported. Dr. Paul P. McCam, superintendent of the present sanatorium, will have charge of both institutions with an assistant superintendent in residence at each.—An oil portrait of Dr. Thomas Clarence Johnson, Lumberton, was presented by his friends in the community to the Thompson Memorial Hospital, Lumberton, September 13. It was hung in the Johnson House, a new nurses' home named for Dr. Johnson.

OHIO

University News—The Alumni Association of Western Reserve University School of Medicine has voted to establish a scholarship in the senior class in memory of the late Dr. Charles Franklin Hoover, professor of medicine from 1909 to 1927.

Institute on Cardiovascular Disease—The Academy of Medicine and the Heart Council of Greater Cincinnati will conduct their fifth annual institute on cardiovascular disease,

October 26. The guest speaker will be Dr. Horace M. Korr, professor of the theory and practice of medicine, State University of Iowa College of Medicine, Iowa City, who will lead a round table discussion on "The Treatment of Congestive Heart Failure" and give an address on "The Nature and Manifestations of Congestive Heart Failure." Clinical lectures and demonstrations will be held in the Cincinnati General Hospital.

PENNSYLVANIA

Society News—Dr. Leslie B. Hohman, Baltimore, addressed the Lycoming County Medical Society, Williamsport, October 5, on "Intelligent Diagnosis of the Neurotic."—The Venango County Medical Society was host to physicians of several surrounding counties September 24 at an open meeting with the following speakers: Drs. Roy R. Snowden, Pittsburgh, on "Medical Management of Hypertension"; Huo Roesler, Philadelphia, "Hypertensive Heart Disease"; John A. Kolmer, Philadelphia, "Septicemia"; George W. Crile, Cleveland, "Surgical Treatment of Hypertension"; and Maxwell J. Lick, Erie, president of the Medical Society of Pennsylvania.

Philadelphia

Personal—Dr. Dean A. Collins, formerly of Minneapolis, has been appointed assistant professor of physiology at Temple University School of Medicine.

University News—The 113th annual session of the Jefferson Medical College was inaugurated, September 20, with George Russell Bancroft, D.Sc., professor of physiologic chemistry and toxicology at the university, delivering the introductory lecture on "Some Goals in Medical Study."—Dr. Elliott P. Joslin, Boston, gave an address at the opening of the fall term of the Hahnemann Medical College of Philadelphia, September 27, entitled "Opportunities for the Medical Student."

Pittsburgh

Three Year Study of Fever Therapy—The Westinghouse Electric and Manufacturing Company has given \$50,000 to the University of Pittsburgh School of Medicine to support a three-year program of research in fever therapy. The study will provide data on humidity and temperature as it affects the human body. The aims of the study are:

1. To make fever therapy facilities more readily available in the Pittsburgh district.
2. To conduct concentrated clinical investigations into the further treatment of diseases using this method, chemical methods and combinations of the two and to make studies on a variety of diseases including those now treated with fever and others.
3. To make a critical study of all means of creating fever in an effort to discover the safest, simplest method with respect to mechanical operation, reliability, safety and in predetermined atmospheric environments.
4. To accumulate more knowledge concerning the reactions of microorganisms to their environmental conditions, particularly their reactions to heat including virulence, multiplication, growth and death.
5. To train personnel and to provide information for the medical profession and the public concerning the value of this type of medical procedure.
6. To make data of these studies available in determining proper atmospheric conditions among industrial workers as well as serving as a medical study for the comfort of man.

The study will be directed by the department of industrial hygiene of the school of medicine and affiliated hospitals. Hospitals in this group not already having fever therapy apparatus will install equipment within the next few months.

UTAH

Plague Infection—Under date of September 2, plague infection was reported to have been demonstrated by animal inoculation in tissue from a ground squirrel (*Citellus armatus*) shot August 19 west of Strawberry Reservoir, twenty-one miles southeast of Heber, Wasatch County, according to *Public Health Reports*.

VIRGINIA

Personal—Dr. George A. Wright has resigned as superintendent of the Southwestern State Hospital, Marion, to be effective December 1.—Dr. William B. Porter, Richmond, received the Jefferson Gold Medal of the Virginia Academy of Science at the recent annual meeting.

Society News—Dr. Charles C. Haskell, Richmond, addressed the Mid-Tidewater Medical Society recently at Gloucester Court House, on digitalis.—Drs. William L. Peple and Samuel W. Budd, Richmond, among others, addressed the Southside Virginia Medical Association in Burkeville, September 14, on "Further Observations on Management of Cancer of the Cervix."—The Southwestern Virginia Medical Society held a meeting at Mountain Lake, September 3, at

which invited guests included Drs Otis L Anderson and Lee E Sutton Jr, Richmond, who spoke on diagnosis and treatment of early syphilis and congenital syphilis, respectively

WISCONSIN

State Medical Election—Dr Albert E Rector, Appleton was chosen president-elect of the State Medical Society of Wisconsin at its annual meeting in Milwaukee, September 16, and Dr James C Sargent, Milwaukee, was inducted into the presidency. The next annual session will be held at Milwaukee in September. At the annual dinner of the society the council award for distinguished service to medicine and the public was presented to Dr Joseph F Smith Wausau. Dr Stephen E Gavin, Fond du Lac, retiring president, made the presentation to Dr Smith, who is the twelfth recipient to receive the award in the last seven years.

HAWAII

Society News—The council of the Hawaian Territorial Medical Association held the first of its newly initiated meetings, September 2-3, in Honolulu. The meetings, which will be held in September and February of each year, are to be attended by councilors and vice presidents of the association to discuss various medical problems of general interest.

Smallpox Develops at Sea—According to *Public Health Reports* a case of smallpox (varioloïd) occurred in a steerage passenger on the British steamship *Empress of Asia* which arrived at Honolulu September 5. The case was recognized by the ship's surgeon two days before the vessel arrived. The patient was taken to the ship's hospital and all third-class passengers and crew contacts were vaccinated. Those failing to show an immune reaction were detained at quarantine, while the others were released.

GENERAL

Specialty Board Examination in Psychiatry and Neurology—The next examination of the American Board of Psychiatry and Neurology will be held in New York, December 28. Applications to take the examination must be in the hands of the secretary, Dr Walter Freeman, 1028 Connecticut Avenue, Washington, D C, by October 25.

Health Exhibit at Golden Gate Exposition—The prevention of disease rather than its treatment will be the theme of the health exhibit planned for the Golden Gate International Exposition in San Francisco in 1939. A committee composed of representatives of medical and allied agencies in California has been appointed to work out the details of the health exhibit with Milton Silverman, head of the health and science division.

Society News—Dr Frank B Dorsey Jr, Keokuk Iowa, was chosen president-elect of the American Association for the Study of Gout at its annual meeting recently and Dr Frank H Lahey, Boston, was installed as president. Dr William Blair Mosser, Kane, Pa, is the secretary. The next annual meeting will be held in Washington, D C, in September. At the annual session of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons recently Dr James E King, Buffalo, was named the president-elect and Dr Paul Titus, Pittsburgh, was installed as president. Dr James R Bloss, Huntington, W Va, is the secretary.

Academy of Physical Medicine—The fifteenth annual meeting of the Academy of Physical Medicine will be held at the Hotel Walton, Philadelphia October 19-21, under the presidency of Dr Franklin P Lowry, Newton, Mass. The program will include the following speakers:

Sir Robert Stanton Woods London England Organization of a Physical Medicine Unit in a Teaching Hospital
Dr Chevalier L Jackson Philadelphia Electrocoagulation Through the Bronchoscope in the Treatment of Bronchial Tumors
Robert S Harris Ph D Cambridge Mass Medical Application of Radiant Energy
Dr Frederic Jay Cotton Boston Physical Therapy in Industrial Disease
Dr William B Snow New York Further Advances in Fever Therapy Improvement in Technique and Routine for Fever Therapy
Dr Isidore Gunzburg Antwerp Belgium Treatment of Rheumatism by Infra Red Hyperthermic Bath
Dr Martha Brunner Ornstein Vienna Short Wave and Ultra Short Wave Therapy

Rocky Mountain Medical Journal—Beginning with the January issue, *Colorado Medicine* will be known as the *Rocky Mountain Medical Journal*. When the change is effected the new publication will embrace the state of Utah, which has been publishing its own journal as a quarterly. The house of delegates of the Utah State Medical Association voted September 3 to enter into an agreement with the Colorado State Medical Society whereby we may cooperate with them in the maintenance of the *Rocky Mountain Medical Journal* the details of

such agreement to be left to the Council. The journal will continue to represent the Colorado State Medical Society, the Wyoming State Medical Society and the Colorado Hospital Association, and ownership of the publication will remain with the Colorado State Medical Society.

American Board Examination in Obstetrics and Gynecology—The American Board of Obstetrics and Gynecology will hold its next examinations for group B candidates in various cities of the United States and Canada on Saturday Nov 6, 1937, and Saturday Feb 5, 1938. Application for admission to these examinations must be filed on an official application form in the office of the secretary at least sixty days prior to these dates. The general oral, clinical and pathologic examination for all candidates (groups A and B) will be conducted by the entire board, meeting in San Francisco, June 13-14, 1938, immediately prior to the session of the American Medical Association. Application for admission to group A examinations must be on file in the secretary's office before April 1. Further information and application blanks may be obtained from Dr Paul Titus, secretary, 1015 Highland Building, Pittsburgh, Pa.

Association of Medical Colleges—The forty-eighth annual meeting of the Association of American Medical Colleges will be held at the Fairmount Hotel, San Francisco, October 25-27, under the presidency of Dr Edward Stanley Ryerson, Toronto. A symposium on examinations will open the session Monday morning with the following speakers:

Dr Ewen M MacEwen dean State University of Iowa College of Medicine Iowa City
Dr Harold S Diehl dean of medical sciences University of Minnesota Medical School Minneapolis
Dr Richard B Dillehunt dean University of Oregon Medical School Portland

A symposium on the community aspects of medicine will be conducted by the following:

Dr Harry R Wahl dean University of Kansas School of Medicine Kansas City
Dr Benjamin W Black Oakland director Alameda County Institutions
Ralf Couch A B secretary University of Oregon Medical School

Other speakers on the program will include:

Calvin P Stone Ph D Stanford University Calif and Dr George S Johnson San Francisco professors of psychology and medicine (neuropsychiatry) respectively Stanford University Integration of the Teaching in Psychology and Psychiatry
Drs Franklin G Ebaugh professor of psychiatry, and Maurice H Rees dean University of Colorado School of Medicine Denver Teaching of Psychobiology by Means of Personality Study
Dr Ryerson Cultivation of Health in Relation to the Medical Curriculum

Government Services

National Advisory Cancer Council Formed

In conformity with the National Cancer Institute Act, signed August 5, the following persons have been appointed to form the National Advisory Cancer Council, it was announced September 29.

Dr James Ewing director of cancer research Memorial Hospital and professor of oncology at Cornell University Medical College New York
Dr Francis Carter Wood director of the Institute of Cancer Research Columbia University College of Physicians and Surgeons New York
Clarence C Little Sc D Bar Harbor Maine head of the Roscoe B Jackson Memorial Laboratory and managing director American Society for the Control of Cancer
Arthur H Compton Ph D professor of physics University of Chicago Chicago
James B Conant LL D Cambridge Mass president Harvard University

Dr Ludwig Hektoen professor and head of the department of pathology Division of Biological Sciences University of Chicago director John McCormick Institute for Infectious Diseases and chairman division of medical sciences National Research Council

A meeting of the council is tentatively planned during the month of October to consider rules and regulations on the basis of which grants in aid will be made to further promising cancer research projects, to determine rules and regulations under which fellowships will be established, and to set up minimum requirements with regard to the facilities of treatment centers to which radium will be lent, all of which are in accordance with the stipulations of the recently enacted law. The National Cancer Institute will be erected on the site at Bethesda, Md, recently donated by Mrs Luke Wilson and her son. It will be part of the National Institute of Health in the U S Public Health Service which is under the directorship of Asst Surg Gen Lewis R Thompson. A director for the cancer institute has not yet been named but Dr Thomas Parran surgeon general of the public health service, will serve as ex officio chairman of the council.

LONDON

(From Our Regular Correspondent)

Sept. 18, 1937

Services of Missionary Hospitals to the Wounded in China

The secretaries of the British missionary societies have held a conference in London regarding the present emergency in China. The meeting was impressed with the unprecedented opportunity of rendering medical and refugee service to troops and civilians alike in areas where fighting is taking place. Various missionary hospitals are well situated to serve the needs of the different localities affected. The conference felt that each society should make determined efforts not only to maintain their regular hospital work but to increase and strengthen their personnel and equipment, so as to render help to war victims without respect to nationality. These hospitals are in many cases desperately crowded with patients. The doctors and nurses are overwhelmed with demands on their time and strength, and it is likely that, with the development of aerial war and attempts to bomb inland cities, medical services will be called for on a continuously larger scale and over a wide front. The efforts to enforce any kind of blockade of China make it urgent that medical supplies should be dispatched as early as possible. It is hoped that hospitals will also be made available as bases from which mobile units may be organized. The chief hospitals concerned are those of the London Missionary Society at Tientsin and Tsangchow, the Methodist Missionary Society Hospital at Wutung, the Kaifung hospital of the China Island Mission, the Taiyuan hospital of the Baptist Missionary Society, the S. P. G. hospital at Tatung and the Cheloo Union Hospital, for which various missionary societies are responsible, as well as some American bodies. All these hospitals have from forty to 150 or more beds. The Quakers have no work in the area at present affected by the hostilities, but one of the last acts of the Quaker World Conference, recently held at Philadelphia, was to endorse proposals for a Quaker center in Shanghai similar to the centers in many European capitals.

Treatment of Bladder in Spinal Injuries of War

At the Section of Urology of the Royal Society of Medicine, Sir John Thomson-Walker read an important paper in which he said that the treatment of the bladder in the large number of cases of spinal injury was one of the surgical failures of the Great War. The probable cause was that the methods used in peace were unsuitable in war, partly because of the surroundings and partly because of the varying ability and lack of coordination of those through whose hands the wounded had to pass. Destruction of the supralumbar cord at any point was followed immediately by complete retention of urine. After a variable time the lumbar center recovered tone and involuntary micturition was established. In the large number of cases under Thomson-Walker's care these two stages were clearly defined. The average duration of the retention in thirty consecutive cases was fifty-five days, the shortest being twenty-four hours and the longest eighteen months. After some days or hours the urine began to dribble away, the bladder remaining distended (retention with overflow). The stage of periodic reflex micturition (the automatic bladder) began gradually there being a transition period of partial distention in which periodic contraction expelled a quantity of urine. In the fully developed stage of periodic reflex micturition the bladder was a purely reflex organ with a capacity varying from 2 to 12 ounces or more and involuntary micturition occurring at intervals of from a quarter of an hour to two or three hours.

In his extensive experience as genito-urinary specialist in the great military hospital, Thomson-Walker found urinary sepsis

so frequent that the death rate from it in spinal cases was 80 per cent—a lamentable tale of surgical failure. How was it brought about? The universal treatment of the bladder was intermittent catheterization. Septic catheterization was responsible. The catheter was passed as early as possible and used as frequently as circumstances permitted. After each passage the bladder became distended with grossly infected urine and the infection passed to the kidney. Thomson-Walker discussed the alternative methods of treatment: (1) nonintervention, (2) expression of bladder contents by pressure and massage, (3) the tied-in catheter and (4) early or prophylactic cystotomy.

1. An American surgeon, E. A. Besley (*THE JOURNAL*, Aug. 25, 1917, p. 638), strongly recommended that the bladder be allowed to distend until overflow takes place and eventually periodic micturition is established. He has seen no damage result to bladder or kidneys, but rupture of the bladder has been recorded by others. Thomson-Walker has had no experience with this method and without more evidence that it is without deleterious effect does not recommend it for universal adoption.

2. In some cases the expression of the bladder contents by pressure and massage is easy, in others difficult. It should be begun before distention is marked, when the method is painful. Contraction of the bladder sphincter is a difficulty. Cases of rupture of the bladder by this method were often spoken about during the war, but figures are not available. There is a danger of this complication when a large number of medical officers and orderlies, of varying skill, use the method. It is entirely unsuited for cases of established urinary sepsis.

3. With the tied-in catheter cystitis will probably develop but as there is free exit infection does not ascend to the kidney.

4. During the war Thomson-Walker advocated entire avoidance of the catheter and drainage of the bladder by suprapubic cystotomy. He did not expect to avoid cystitis entirely, but distention of the bladder with septic urine in the intervals between catheterizations, which caused ascending pyelonephritis. It gave good results in some cases. Objections to it are that it is difficult to get water-tight drainage and that cystitis is certain to develop. But cystitis without intravesical pressure is not dangerous.

In the discussion, Sir Alfred Webb-Johnson said that an authoritative statement that a catheter should never be passed in the presence of a spinal injury would save many lives. In the war he persuaded the Red Cross to erect a hut in which were concentrated such cases of spinal injury. It proved difficult to get hold of cases of "virgin bladder," for either in the ambulance train or at the casualty clearing station somebody was pretty sure to have insisted on passing the catheter. In sixty-six cases on which they were able to concentrate, both the expression method and the nonintervention method were carefully tried. Neither method was perfect, but each was worth a trial. It soon became evident that the expression method must not be left to a heavy-handed orderly and but seldom must be entrusted to a nurse, though it could sometimes be carried out by a well-instructed sister. The great differences between bladders were illustrated as soon as an attempt was made to empty by expression. Yet it was possible at one time to walk into that hut of twenty beds and see twenty specimen glasses of urine all quite clear and free from infection.

The Prevention of Catgut Tetanus

For the prevention of tetanus resulting from the use of catgut in operations, the minister of health has issued new regulations. Catgut which is sold under his license under the Therapeutic Substances Act is free from any risk of infection as its manufacture is strictly controlled and it is properly sterilized before being put on sale. But deaths from tetanus due to the use of catgut that has not been so sterilized occur from time to time. The new regulations require all ligatures and sutures which are not sold under the Therapeutic Substances Act to bear a label stating in prescribed terms the

efficient sterilization is necessary before use. By this safeguard surgeons will be able to distinguish at once ligatures and sutures that require sterilization from those which do not.

PARIS

(From Our Regular Correspondent)

Sept 18, 1937

Chair of Social Medicine in Medical School

The municipal council of Paris has arranged with the Faculté de médecine to organize a department of social medicine. This is necessitated by the rapid development of the laws of social aid and the widespread application of public welfare movements and social insurance in this country. An appropriation was made by the council for the salary of the head of this newly created teaching department. In a book published in 1925 as a part of an encyclopedia of clinical medicine, Dr Louis Guinon stated that social medicine includes social hygiene and the legislation incident thereto, as well as a study of the sociological, economic, political and pedagogic factors which permits its organization and extension in the world. In enumerating the various branches of medicine that would be included it is evident that no sharp line of demarcation was made by Guinon between social medicine and hygiene on the one hand and general medicine on the other. Hence according to Dr Noir, in a recent editorial in the *Concours médical* a great deal of study will be necessary to define the scope of teaching of the newly created chair of social medicine. The latter ought only to take up legislation on the subject and its practical application.

First International Congress on Infantile Psychiatry

At the meeting of the first International Congress on Infantile Psychiatry, July 24-31, in Paris, the question of psychiatry in school children was the subject of a number of papers. There was a unanimity of opinion on the importance of this problem from the point of view of prophylaxis of crime and recuperation of the socially handicapped. The necessity of having specially trained teachers in the classes for such children was emphasized. It is essential to make a distinction between simple mental debility and the abnormals with well defined troubles, such as the schizophrenic, impulsive and perverse types. The psychologic and analytic pedagogy must vary according to the individual case. It is also essential to take into consideration the family environment and its reactions on the child, in order to clear up certain disturbances. Mental debility as a cause of infantile and juvenile delinquency was discussed by foreign and French physicians who had a large experience in juvenile courts. It was generally agreed that mental debility cannot be considered as the only cause of delinquency, constituting only about 27 per cent of all the cases. Troubles of character, the influence of education and the social surroundings account for many of the cases. The mentally debilitated child lacks the capacity to discriminate, is impulsive, is easily influenced and, as the result of making a failure of his life, needs money and is thus led to commit criminal acts. The majority can be educated, only those presenting serious character changes being incorrigible. Delinquent children are more commonly found when the family environment leaves much to be wished for or when the parents have been divorced or, finally, in the case of children who have been abandoned.

The Model Village at the 1937 Paris Exposition

In an article in the August 1 issue of the *Suède médical* is a description of one of the exhibits, the model village, at the exposition. The author states that too many villages in France have not kept up with the progress made in sanitary methods. It is a common sight to see a manure pile in front of the farm house and the liquid portions finding their way into the streets. The stables are dark and poorly ventilated, the living rooms often built directly on a level with the soil, with comparatively few windows and the bedrooms poorly ventilated. For drink-

ing, washing and cooking purposes, water of doubtful purity from a well or other source situated dangerously close to out-houses is still used. Of 38,000 townships in France, there are 20,000 without a central water supply. The model village is an effort to show how the conditions just enumerated can be and are already being corrected. The model is constructed for a village of from 1,500 to 2,000 inhabitants, the town hall forming the nucleus as it does in all French country towns. At the schoolhouse the principles of hygiene will form an important part of the curriculum, and there is a building in which the various agricultural cooperatives will be sheltered. A model village home is shown which consists of well aerated rooms and better toilet facilities than is at present deemed necessary. Stables for horses and cattle with ideal sanitary conditions, as yet rarely to be seen in France, are shown. Every method of securing a better water supply for small agglomerations forms a part of the exhibition.

Negative Tuberculin Skin Reactions in Children

Prof F Bezançon and associates read a paper at the July 20 meeting of the Académie de médecine entitled "Tuberculous Contagion of Children in Infected Families." They said that observation over a fifteen year period in Bezançon's hospital and dispensary service revealed cases of children who, although exposed in their homes to prolonged contact with tuberculous parents, not only failed to present any clinical or radiologic evidence of the disease but also never had a positive skin reaction to tuberculin. The histories of ten families, of from five to eight children each in which one or both parents were tuberculous, observed for from ten to fifteen years, were cited. In only twenty-two of thirty-six children was the skin reaction markedly positive from the time at which it was first made. In six cases it remained constantly negative and in ten cases the reaction suddenly changed from negative to positive, although exposure to the disease had existed for years. The persistence of negative reactions, in spite of prolonged, close and constant contact with tuberculous parents in very unhygienic surroundings again shows the complex nature of the problem of the etiology of tuberculosis. The law of age could not be invoked in the cases observed by the authors. There appear to be some secondary factors, such as digestive disturbances, climatic and seasonal influence, psychic and moral causes, concerning which much remains to be learned.

A paper entitled "Significance of Negative Cutaneous Reactions to Tuberculin" was read by one of Bezançon's associates, who studied 105 children in fifty-three families in which one or both parents were tuberculous. Of the 105 there were negative reactions in seventy-two and positive in thirty-three. A number of cases were cited in which, although all the children had been equally exposed, some, in the same family, had positive and others a negative reaction. In many, the negative reaction changes suddenly to a positive one after an interval of from four to fifteen years. This is frequently seen in students and nurses who work in wards for cases of pulmonary tuberculosis. The problem of why such a sudden change of reaction occurs still requires study.

The discussion was opened by Professor Guérin of the Pasteur Institute, who said that the observations of Bezançon and his associates seemed to set up the theory that in the human race there was an initial period of infection which might be termed "preallergic," of long duration and without a positive tuberculin skin reaction. Professor Marfan defended the value of the epidermal tuberculin test. He had always found lesions when it was positive. Professor Rist stated that he did not believe that any evidence presented so far should lessen confidence in the value of the tuberculin epidermal and dermal tests. Professor Debré maintained that an anteallergic period could exist for some length of time, but it did not seem plausible for a person to be a carrier for years and not to react to increasingly stronger doses of tuberculin, in the form of cutaneous reactions.

Cutaneous sensibility to tuberculin ought to be tested, vigorously but cautiously, before being considered negative. Until more proof was offered, his faith in the tuberculin skin tests would remain unchanged. Professor Lesne expressed confidence in the positive epidermal reaction as signifying the existence of an unquestionable contamination. In closing, Professor Bezançon said that he did not wish to be understood as questioning the value of the cutaneous reactions but he said that it was advisable to search for certain factors which cause them to appear very late or which give rise to anteallergic periods.

International Congress of Public Health Officials

The International Congress of Public Health Officials, organized by the French Public Hygiene Society, will be held in Paris, October 20-21. Papers will be read by public health officials of various countries on the role which they should play in modern society.

Epidemic of Poliomyelitis in Victoria

During the past three months an epidemic of poliomyelitis has been slowly spreading in an area of about 15 miles in width in the suburbs of Melbourne, Victoria. So far there have been forty-seven cases with five deaths. There is evidence that the epidemic is of a widespread scattered nature throughout the state. An effort is being made to limit the spread by imposing restrictions on interstate travel, especially of children. A medical committee controls the joint government and municipal campaign against the disease, and seventy-four state schools have been closed. In view of the state of flux through which the treatment of the disease is passing, it is interesting to note the public statement which the medical committee has issued to the inhabitants of the infected area. "At present there is great doubt amongst world authorities as to the value of convalescent serum in the treatment of poliomyelitis as hitherto and at present employed. This doubt is supported by experience in the present epidemic. Serum, however, is at least harmless and, as there is no other form of treatment available, and it is possible that a more potent serum may be developed, the committee feels that the collection of serum should be continued until more definite knowledge is available. With regard to the use of nasal sprays, the committee feels that, in view of the inconclusive results of a trial of the picric acid-alum spray in a large epidemic in America, it is not yet in a position to recommend the general use of such a spray. Any persons who wish to adopt this method should do so under medical advice. The committee considers that the intramuscular injection of citrated blood from parents to children who are known to have been in contact with a case may help to avert an attack and would be harmless. Closure of schools can be a useful measure only if parents ensure that their children are strictly isolated in their homes for at least one month."

The Future of Medical Practice in New Zealand

Medical practice in New Zealand is at the crossroads. The government has the ambition of providing a complete health and medical service for the people of New Zealand whereby the best possible service is available, free of charge, to all members of the community irrespective of their financial situation. The government desires to give every citizen sound physical health and a longer expectation of life through free advice and treatment from the best doctors available. As one member of the government, Dr. T. G. McMillan, the member for Dunedin West, expressed the government's ambition: "We do not want a medical service geared by the poor man's pocket, but we want the best available to every one in the dominion." He further stated that it was hoped to improve the personal relationship between patient and doctor by removing the general

cause of irritation between them—the fee. It is considered that this has been an economic barrier which has been responsible for the tragic failure to prevent incurable disease. The New Zealand branch of the British Medical Association, through its president, Dr. T. D. M. Stout, has stated that it would act in the fullest cooperation with the government. But at the same time the association is doubtful whether any scheme embracing a large section of the community is either necessary or desirable. Adequate provision, however, with a full health service, should be made available to people not able to make financial provision for it themselves. The government has stated that it does not contemplate any scheme which will react detrimentally on the profession as regards either its earning or its professional standard. The British Medical Association considers that the development should be of an evolutionary nature and that it should start with the class of people of the lowest income groups, with the possible addition of other sections of the people as the scheme develops.

A special committee, consisting of members of parliament and department officers has been appointed by the government, and this committee is examining all aspects of health insurance. An opportunity will be provided for interested parties to appear before a select committee of the House of Representatives to make any further suggestions or recommendations they wish to do. To assist in the preparation of a satisfactory scheme of national health insurance, Sir Henry Brackenbury is coming to New Zealand on the invitation of the New Zealand Branch of the British Medical Association and will arrive early in September. Sir Henry Brackenbury, who was a noted British authority on the medical aspect of national health insurance, will spend about three months in the dominion. At present the public hospitals of New Zealand are maintained by government subsidies, by local taxes and by patient's fees, but these charges are not nearly sufficient to cover the cost of maintenance and a large proportion of the patients who receive either inpatient or outpatient treatment pay nothing at all. It is significant that the "means" test for outpatients at the Wellington Hospital has been abolished. According to the hospital act, and to the practice of the controlling authorities of the larger hospitals the wards of public hospitals are open to all classes of the community, rich or poor alike.

Great building schemes are in contemplation. It is considered in New Zealand that £1,250 is nowadays by no means too large a sum to spend on the capital cost of a bed in a public hospital. The hospitals are developed to a high state of efficiency as regards equipment, with a corresponding increase of expenditure to a degree not originally contemplated. Maintenance increases have resulted from the adoption of the forty hour working week, which has been ordained by the present government, and wages have been considerably increased. In the Wellington Hospital, for instance, last year's expenditure in salaries and wages was £62,448 and this year it will be greatly increased, for the items of the wages of the male attendants alone in the hospital has increased by 40 per cent in the hospital board's estimates.

THE ECONOMIC ASPECT

The population of New Zealand, including Maoris, at the last census was rather more than one and a half million. It is proposed to pay doctors at the rate of £1 per head annually as a retainer. All materials and other expenses will be absolutely free to patients and will be paid for by the government. It is estimated that the cost of the health scheme contemplated by the government is three and a half million pounds annually. This would be equivalent to a tax on wages, and on income other than wages, of seven pence in the pound. If the population was distributed among the medical practitioners, each doctor having his own list, there would remain a sum in the vicinity of two million pounds for extra services. It is believed that the proposal involves free medical and nursing service in

maternity cases, involving from fifteen to twenty pounds in each case. This would require about another half million pounds. The scheme would provide also for special hospital attention, traveling expenses of doctors and patients, and the provision of special homes and hospital staffs.

At present the burden on taxpayers for hospitals and for all local, municipal and borough services is inequitable. It seems that the increasing cost of hospitals in New Zealand is extravagant. Paying wards in hospitals are said to be undemocratic. Experience has shown that original estimates of hospital and other costs for medical services cannot be made proof against increasingly mounting expenditure, and there is a feeling that a stage of expansion will be reached when even a state with all its powers of taxation will find its financial burden too great to bear. The tendency toward the abolition of honorary staffs, and the substitution therefor of paid full time or part time surgeons and physicians, will itself mean a large increase of expenditure. Four large metropolitan hospitals at present require new treatment machines for high voltage roentgen therapy. This is estimated to cost £36,000.

It is considered that the complete nationalization of public hospitals will be the inevitable outcome of the government in its attitude toward medical services. At present in New Zealand the state pays the whole cost of schools, and the education system generally, from taxation funds. And the same principle is intended to apply to medical service. There is a marked socialization trend in New Zealand today. Ownership of property has become extensively socialized with the system of state lending for homes on a very narrow margin of security, with the result that the average wealth of taxpayers is very low. The tax burden, moreover, apart from the cost of maintenance of hospitals, has increased with the development of other social services and schemes of municipal progress.

Consumption of Food Contaminated with Poison Gases

Dr Albert Telbisz, captain in the medical corps of the Hungarian army, in a recent lecture before the Royal Medical Society said that with regard to the consumability of food articles containing war gases one must pay attention to its water content. In general war gases penetrate deeper in foods containing much water, therefore foods containing much water retain the characteristic smell of the gases and for this reason they are unsuitable for human consumption. Phosgene, which speedily disintegrates and loses its action, at the worst merely spoils the taste of the food, rendering it less enjoyable. Real danger is caused only by the consumption of foods soiled with mustard gas or mixtures containing arsenic and chlorpicrin, which are insoluble in water. The flesh of a recently slaughtered animal takes up much more from mustard gas than cooled or frozen meats. Also milk, owing to its fat content, may retain a greater quantity of mustard gas in solution through a much longer time, without the decomposition of the mixture. Mustard gas can penetrate into the flesh of an unpeeled apple to a depth of from 3 to 5 mm, while the skin of oranges and lemons gives a natural defense. On the surface of the potato gases spread quickly and penetrate deeply. At the site of the absorption in the whitish inner part of apples and potatoes sharply delineated brown spots of characteristic odor occur.

Gas-proofing methods for food articles are yet undeveloped. Sure prevention can be obtained only by strictly forbidding the consumption of contaminated water and destruction of soiled food. Water can be saved by keeping it in reservoirs or covered cisterns. Of course in such a way only small quantities of water can be protected. Foods can be protected by packing them in small quantities in water proof paper or cellophane

or, if the quantity is greater, they can be covered with a water proof material. These protective measures should be resorted to in every case, for it is doubtless easier to protect the foods than to rid them of absorbed gases. Nevertheless, however careful and cautious one is, there may be instances in which food or drinking water has to be rendered gas free. For food the simplest and at the same time cheapest method is thorough ventilation. In a similar way meat or lard containing phosgene can be gas proofed. In such cases gas proofing with diluted soda solutions is superfluous, because this would greatly interfere with the preservation of flesh. The rinsing water of meat soiled with mustard gas and also the soup of the cooked meat must be poured out. The mustard gas suspended in such water can be rendered innocuous by chlorinated lime. If meat has been reached by a quantity of mustard gas spray, or rain, its surface should be washed with soda solution and the upper layer should be cut off with a knife having a wide blade to a depth of half an inch. Soaking the meat in a solution of potassium permanganate, from 3 to 5 per cent, as suggested by several authors, is a doubtful way of gas proofing. With chlorinated lime or its watery solution, gas proofing is much more efficacious, but in practice this method has not proved satisfactory because the meat absorbs the characteristic odor of chlorine and renders it distasteful. Meat cannot be efficaciously gas proofed by fumigation either. If meat has been reached by enough mustard gas to cover its whole surface it has to be destroyed. If only the vapor of mustard gas has reached the meat, thorough ventilation suffices to render it edible. Dr Telbisz concluded by stating that the selection of the proper method for gas proofing is not easy but is important, because in time of war there is a scarcity of foods.

Serving of Wine Obligatory in Restaurants

To serve the interests of wine growers, the government enacted some years ago a regulation that every soldier shall be rationed half a liter of wine daily into two portions, to be consumed with luncheon and supper. Since that law was enforced conditions have not improved but have become worse. To save the wine industry, the government enacted some days ago that in all restaurants the menu shall include a portion of wine, whether the customer wants it or not. As the menu system prevails only in the better class restaurants, this enactment is of no major practical importance. A part of the press strongly condemns this arrangement, especially since in Budapest there are many temperance restaurants. A medical journal ironically remarked that it is fortunate that the government did not enact that school children in place of their free tumbler of milk at 10 a. m., should get a portion of wine.

Work of the Rockefeller Foundation in Hungary

The Rockefeller Foundation made the first step toward rehabilitating the scientific institutes of Hungary in 1920. Since that time \$1,100,000 has been given. In the first years the foundation supplied the deficiencies of the equipments of the universities, which were run down in consequence of the war. In 1925 a public health reform bureau was established to initiate and develop the organization of the so called Green Cross Protection of Family life. In 1925 the Rockefeller Foundation granted money for the erection of the National Public Health Institute. In 1927 support was granted to the erection of the Nurses' Training Institute soon afterwards it helped to erect the Institute for Training Maternity Staff. The help given in the erection of the National Public Health Institute deserves special mention. The foundation rendered the notification of infectious diseases possible and an extensive system of laboratory examinations. This institute initiated the testing of drugs and proprietary medicines, the starting of a systematic campaign against malaria, miners' phthisis, flies, and so on, the organization of prophylactic inoculations against

diphtheria, and the production of vaccines. It has also resulted in more foreign physicians coming to study.

When John D. Rockefeller died, the Hungarian ambassador in Washington laid a wreath on the coffin of the great patron of Hungarian scientific work.

Centenary of Budapest Royal Medical Society

The Budapest Royal Medical Society recently celebrated the centenary of its foundation, on which occasion Tiburtius Verebelyi, professor of surgery at the Budapest University and president of the Royal Medical Society, gave an address. He said that without doubt the last hundred years had seen more medical progress than any other century. From the stethoscope to electrocardiography and roentgenology, from the simple steel scalpel to the electric knife, from the clink of the bladder stone to the cystoscope, from sunlight to radiotherapy are a few of the practical achievements in therapeutics and diagnosis. With the deepening of our knowledge and with the recognition of the importance of cooperation, physicians must concentrate now on solving the present hygienic, social and professional problems.

Personals

Baron Alexander Koranyi, late professor of clinical medicine at Budapest University, received the Honorary Doctorate from the University of Athens on the occasion of the centenary of the foundation of the university.

The Ninth International Congress of Military Surgeons and Pharmacists

The Ninth International Congress of Military Surgeons and Pharmacists, under the patronage of King Carol, was held in Bucharest July 2-8 and was opened by Lieutenant General Iliescu in the presence of Costinescu, minister of health, Angelescu, minister of education and the majority of the diplomatic staff. The presidential address expressed thanks to King Carol for his sacrifices in connection with the health of the army and to the royal family for its generosity with regard to the care of the wounded. Speaking about the vocation of the medicomilitary staff, he emphasized that military surgeons need to be possessed of military in addition to medical knowledge. Speaking about the importance of well equipped laboratories, he said that the achievements of laboratories were sooner availed of by the army than by the civilian population. Vaccination against smallpox, for example, was rendered compulsory in the army of Napoleon, May 29, 1811. Inoculations against typhoid likewise were first applied in the armies.

The congress adopted three important resolutions: 1. Certain localities should be utilized exclusively for the medical service and placed under the protection of the Red Cross Society. 2. The application of the Geneva Convention should be introduced within the shortest possible time and its close observance be assured by military service regulations and military law. 3. Increased protection should be allotted to the civilian population so that they may be exempted from the horrors of war.

Colonel Voncken of Belgium said that the convocation of these congresses was inspired by the ideal of peace. If there is no possibility of realizing perpetual peace at least everything possible should be done to humanize war and to mitigate its horrors and atrocities. In this sense it is necessary to establish isolated health centers, to protect these and to establish regulations for the special treatment of the wounded and the civilian population. Committees were appointed which in time of war are to observe that the regulations laid down in international agreement are enforced.

The international character of the congress was shown by the fact that among the lecturers were Rumanians, Italians, Japanese, Swiss, Greeks, Dutch, English, Russians, French,

Americans, Germans and Yugoslavs. The scientific papers were read in the afternoon hours, while the forenoons were utilized for the inspection of Bucharest's public health institutions.

Congress of Sport Physicians

The first Congress of Sport Physicians was held in Bucharest. The first speaker was Kral, lecturer to the University of Prague, who made known the function of his professorial chair, the aim of which is to make students of medicine know the various problems which surround physical education. Professors Mihailescu and Alexiu expounded the importance of the medical control of physical education among university students and those youngsters who partake in so called premedical training. They showed a minutely elaborated plan for the institutional organization of the training of sport physicians. Lascar, colonel in the medical service, and Jonescu dealt with the teaching of sports needed by those suffering from bodily defects. They emphasized the importance of this from the point of view not only of the upkeep of their health, which is impaired by their deformities, but of the improvement that can be brought about by properly applied sports and exercises, under the control of competent sport physicians. Professor Dumitrescu told of his plan for a biotypologic institute along the lines of physical education. He also expounded the practical realization of this plan. Alexiu and Demetrescu illustrated with numerous examples the importance of the medical control of the gymnastic exercises of sport associations. Ulmeanu proposed the organization of physicians dealing with physical education into a society and suggested that the career of sport physicians be regulated according to certain norms. He said that of late years it has been the fashion to have children taught physical culture, mostly by teachers who are self taught and who may do harm by incompetent teaching. Professor Knoll of Hamburg read a paper on factors promoting accidents from sports, Professor Cassini of Rome, a paper on accidents from sports which occurred in Italy during the last decade, Professor Laugier of Paris a paper on biotypology and physical education, Professor Brouna of Liege, a paper on acceleration in function of the heart in connection with physical culture, professor Arnold of Dresden, a paper on physical education as a therapeutic means in certain disease conditions, Professor Nitescu, a paper on the metabolism of creatine bodies in reference to the training of the body, Gontea, a paper on lacticidemia in connection with the training of recruits.

The Celebration of Professor Marinescu

In celebration of Marinescu's laying the foundation of the teaching of neurology in Rumania forty years ago, the *Noua revista medicala* published a bulky commemorative issue. The most prominent professors of the Rumanian universities and some of his most celebrated pupils contributed articles.

Marriages

ROSCOE BENNETT GRAY COWPER, Big Springs, Texas, to Miss Mary Joy Odom of Denton, June 21.

FERDINAND WELEBR, Washington, D. C., to Miss Berta Hanson of Rolla, Mo., July 28.

WILLIAM RIBBLE PRETLOW to Miss May Fletcher Tiffan, both of Warrenton, Va., July 24.

WILLIAM EGBERT KREWSON, 3d, to Miss Mary Elizabeth Britz, both of Philadelphia, June 19.

WILLIAM M. CASHMAN to Miss Ella Harrington, both of Warren, Pa., July 19.

RALPH MARTIN TIDD JR., to Miss Mary Frances Good, both of Erie, Pa., April 7.

SEYMOUR ZUCKER to Miss Cynthia Prince, both of New York, May 23.

ROSELYN TOUFF to Mr. Elias L. Epstein, both of Cincinnati, April 29.

Deaths

Lorenzo B Lockard, Denver, University of Pennsylvania Department of Medicine, Philadelphia, 1894, member of the Colorado State Medical Society, American Academy of Ophthalmology and Oto-Laryngology, American Laryngological Association, and the American Laryngological, Rhinological and Otological Society, at one time professor of anatomy at the Toledo Medical College, laryngologist and rhinologist to the Sanatorium of the Jewish Consumptives Relief Society, Spivak, and the Evangelical Lutheran Sanatorium, Wheat Ridge laryngologist to the National Jewish Hospital, on the staff of St Luke's Hospital fellow of the American College of Surgeons, aged 64, died, July 31, in St Joseph's Hospital, of intestinal rupture

Julius Henry Powers ♂ Saginaw, Mich, University of Michigan Department of Medicine and Surgery Ann Arbor, 1906, for many years councilor of the eighth district of the Michigan State Medical Society, fellow of the American College of Surgeons, served during the World War, past president of the Saginaw County Medical Society on the staffs of the Saginaw County Contagious Hospital, Saginaw General Hospital, St Luke's Hospital and St Mary's Hospital, aged 57 died, July 19, of carcinoma of the intestine

John Taylor Howell ♂ Newburgh, N Y College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1885, fellow of the American College of Surgeons, past president of the Orange County and Newburgh Bay medical societies, consulting surgeon to St Luke's Hospital, librarian to the Newburgh Medical Library, aged 75, died, July 9, of injuries received when struck by an automobile

Samuel Ernest Lambert ♂ Spokane Wash, Medical Department of the University of Alabama, Mobile, 1901, member of the House of Delegates of the American Medical Association in 1920 and 1921, fellow of the American College of Surgeons, served during the World War, member of the staffs of the Deaconess St Luke's and Sacred Heart hospitals, aged 62, died, July 23, of coronary thrombosis

Arthur Lampton Haight, Crystal Falls Mich, Milwaukee Medical College, 1912, member of the Michigan State Medical Society, past president of the Dickinson-Iron County Medical Society, served during the World War, for many years a member and treasurer of the board of education, medical superintendent and owner of the Crystal Falls General Hospital, aged 58, died, July 20

Clarence Allen Good, St Joseph, Mo University of Michigan Department of Medicine and Surgery, Ann Arbor, 1898, member of the Missouri State Medical Association at one time professor of bacteriology and pathology at the Ensworth Central Medical College, on the staff of St Joseph's Hospital, aged 61, died, July 20, in Rochester, Minn, of carcinoma of the prostate

Josiah Payne Thornley ♂ New York University of Virginia Department of Medicine, Charlottesville 1887 Columbia University College of Physicians and Surgeons, New York, 1896, connected with the U S Public Health Service, on the staffs of the U S Marine Hospital and the Gouverneur Hospital, aged 70, died, July 21, in the Presbyterian Hospital, of bronchopneumonia

Clarence Leroy Bock ♂ Muncie, Ind, Indiana University School of Medicine, Indianapolis 1915, past president of the Delaware-Blackford County Medical Society and the Muncie Academy of Medicine, served during the World War fellow of the American College of Surgeons, aged 51, urologist to the Bill Memorial Hospital, where he died, July 24, of coronary thrombosis

Mathew Lyle Talbot ♂ McAllen, Texas, Vanderbilt University School of Medicine Nashville, Tenn, 1900, past president of the Tarrant County Medical Society on the staff of the McAllen Municipal Hospital, formerly on the staffs of the City and County Hospital, All Saints Episcopal Hospital and St Joseph's Hospital, aged 62, died, July 10, of coronary occlusion

Paul Alexander Quick, Muskegon, Mich University of Buffalo School of Medicine, 1874 member of the Michigan State Medical Society, past president of the Muskegon County Medical Society at one time city and county physician aged 84 formerly on the staff of the Mercy Hospital and the Hackley Hospital, where he died July 20 of uremia

Claude Alfred Boseman, Pinebluff N C, University of Pennsylvania Department of Medicine Philadelphia, 1927, member of the Medical Society of the State of North Carolina,

served during the World War, part owner of the Pinebluff Sanitarium, aged 43, died, July 23, of acute morphine poisoning

Frank Lee Biscoe ♂ Wadsworth, Kan, Georgetown University School of Medicine, Washington, D C 1901, member of the Medical Society of the District of Columbia, served during the World War, on the staff of the Veterans Administration Facility, aged 60, died, July 18, of pneumonia

Timothy Thomas Gibson, Knoxville, Tenn, University of Louisville (Ky) Medical Department, 1909, member of the Kentucky State Medical Association, past president and secretary of the Bell County (Ky) Medical Society, aged 53, died, July 26, of cerebral hemorrhage

Augustus W Clayton, San Angelo, Texas Louisville (Ky) Medical College, 1892, member of the State Medical Association of Texas, aged 68, on the staff of the Shannon West Texas Memorial Hospital, where he died, July 2, of Parkinson's disease

Horace Bowen, Montclair, N J, New York Homeopathic Medical College and Hospital, 1889, president of the Hudson County Board of Health, at one time health commissioner of Hudson County, aged 70, died, July 13, of arteriosclerosis and chronic nephritis

Bernard Joseph Lachner ♂ Rock Island, Ill, Jefferson Medical College of Philadelphia, 1906, fellow of the American College of Surgeons, served during the World War, on the staff of St Anthony's Hospital, aged 59, died, July 1, of cerebral hemorrhage

Charles J Otto, Dayton, Ohio, Eclectic Medical Institute, Cincinnati, 1905, member of the Ohio State Medical Association formerly county coroner, aged 57, died, July 26 in St Elizabeth Hospital, of streptococcal meningitis, otitis media and pneumonia

Edward Ernest Parker, South Bend, Ind, Medical College of Indiana, Indianapolis 1898, member of the Indiana State Medical Association, formerly surgeon to the Culver Military Academy, Culver, aged 66, died, July 28, of cerebral hemorrhage

Alfred Frederick Hodgman, Auburn, N Y, Albany (N Y) Medical College, 1888, member of the Medical Society of the State of New York, veteran of the Spanish-American War, county coroner, aged 71, died, July 12, of lymphatic leukemia

Charles George Strobel, Dolgeville, N Y, Long Island College Hospital, Brooklyn, 1888, for many years health officer member of the Medical Society of the State of New York, aged 73, died, July 16, of cerebral hemorrhage and arteriosclerosis

William A Bernard, Woonsocket, R I (licensed in Rhode Island in 1899), formerly health officer of Woonsocket, on the staff of the Woonsocket Hospital, aged 62, died, July 11, of cerebral hemorrhage, hypertension and arteriosclerosis

John Patrick O'Brien ♂ Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, 1910, served during the World War, aged 54, on the staff of the Misericordia Hospital, where he died, July 20, of lobar pneumonia

William L Murphy ♂ Aurora, Ill, Northwestern University Medical School, Chicago 1903, on the staffs of St Joseph Mercy Hospital and St Charles Hospital, aged 58, died, July 25, of angina pectoris

Frederick S Haeberle, St Louis St Louis College of Physicians and Surgeons, 1891, member of the Missouri State Medical Association, aged 70, died, July 14, in the Barnes Hospital, of heart disease

Frederic Henry Moss, Detroit, University of Minnesota Medical School, Minneapolis 1928, resident physician of the Detroit Tuberculosis Sanatorium, aged 39, died, July 26, of chronic myocarditis

Monroe Manges, Buffalo, Cleveland Medical College, 1892, University of Buffalo School of Medicine, 1898, aged 71 died, July 23, in the Buffalo General Hospital, of cerebral thrombosis and arteriosclerosis

Henrietta A Stoffregen Borck ♂ St Louis St Louis Woman's Medical College 1893, Homeopathic Medical College of Missouri St Louis, 1897, aged 68, died, July 24, of cerebral hemorrhage

Eugene G Greer, St Louis, St Louis College of Physicians and Surgeons, 1906 member of the Missouri State Medical Association, aged 57, died July 26, of cerebral hemorrhage

William Wellington Owen, Wading River, N Y, University of the City of New York Medical Department, 1891, aged 79, died, July 11, of chronic nephritis and myocarditis

INCIDENCE OF CORONARY THROMBOSIS IN RELATION TO CLIMATE

To the Editor—The observation has frequently been recorded that the incidence of coronary thrombosis is apparently increased during the cold seasons. In this connection the report by Master, Dack and Jaffe on "Factors and Events Associated with Coronary Artery Thrombosis" (*THE JOURNAL*, August 21) is of particular interest. These investigators analyzed more than 800 clinical attacks of coronary thrombosis in an attempt to ascertain "what factors may have initiated the thrombosis."

Excitement, ingestion of food, infection, tobacco, alcohol, heart failure, time of day and season of year were found to have no significance. Since the observation with reference to season of year is of some importance from the standpoint of both etiology and therapy, I have analyzed the data presented by Master and his associates.

They divided the monthly incidence of 612 attacks of coronary thrombosis into two groups. The October-April or "autumn-winter," group comprised 314 cases, or 51.3 per cent of the total, and the April-October, or "spring-summer," group consisted of 298 cases, or 48.7 per cent. On the basis of these two frequencies the conclusion was reached that "the element of cold therefore seems to have no role in the formation of a coronary thrombus," and again, that "coronary thrombosis occurs irrespective of season or temperature."

When, however, a slightly different division of the published data is made, a wholly different conclusion results. Retaining the dichotomous classification of the authors, I considered two groups: cases occurring during the winter-spring months of December through May, and those noted during the summer-fall months of June through November. The following totals were obtained: winter-spring, 333 of 612 cases, or 54.4 per cent, and summer-fall, 279 cases, or 45.6 per cent. The difference between these two values of 54.4 and 45.6 per cent is 8.8 ± 2.84 per cent. Since the difference is three times as great as its standard error, from a statistical point of view it is highly significant. Such a difference would be expected to occur by chance selection from a homogeneous population about once in 370 times. An alternative analysis of the same groupings by the chi square test of homogeneity gives a value for chi square of 9.5, indicating highly significant heterogeneity between the two groups. Furthermore, the mean of fifty-one attacks per month was exceeded in three of the six winter-spring months of December to May, with an average deviation from the mean of +4.5, while five of the six summer-autumn months of June to November had an attack rate lower than the mean value, the average deviation in this instance being -4.5.

Another significant observation is brought to light from the published material. The mean number of attacks per month based on the total rate of 612 cases is fifty-one and the standard deviation of monthly incidence is ± 9.5 . Ninety-nine per cent of all values in a symmetrically distributed series are expected to fall within the range of the mean plus and minus two and a half times the standard deviation in this case between the extremes of 26 and 75. The attack rate in every month but one falls well within these limits. The exception occurs in the month of January, a cold winter month which attains the upper limit of this range with a frequency of seventy-five attacks. Statistically this deviation from the mean is regarded as significant.

The foregoing analysis indicates that the onset of coronary thrombosis in the cases reported by Master and his associates was significantly more frequent in the period from December to May than in the period from June to November. Moreover, the factor that contributed most to the increased incidence during the winter-spring months was the significantly high rate

occurring in January. The extraneous influence of temperature, hours of sunshine and meteorological states, which might be at least partly responsible for this differing incidence, is at present a matter for conjecture. The fact remains however that the reported material points to season of the year as a significant factor in the occurrence of the clinical picture of coronary thrombosis.

A PINWHEEL FOR NEUROLOGIC EXAMINATION

To the Editor—In *THE JOURNAL*, July 31, page 346, Dr. E. L. Stern describes an instrument for localizing pain. This instrument was introduced by me in Germany in 1930 (*Arch. f. Psychiat.* 92:474, 1930; *Nervenarzt*, 1930, p. 594; *Bing Lehrbuch der Nervenkrankheiten*, ed. 4, 1932, p. 8) and has been since widely used in Europe. This small instrument has proved during these eight years to be of such definite value that it has become, like the reflex hammer, an indispensable part of the outfit for everyday neurologic practice.

In testing the sensibility of the skin to pain, both for the first gross orientation and for exact determination of the boundaries of hypalgesia or analgesia, it is essential to apply on an extensive area of the skin a series of stimuli which should be as much as possible equal with regard to time, distance and strength. Ordinarily a pin was used for this purpose, but the

Pinwheel for neurologic examination

equality of applied stimuli can be better achieved by a pinwheel which is constructed in the same manner as a copying wheel as used by tailors.

The handling of this pinwheel is easy and convenient. It is rolled under light pressure on the skin or permitted to work with its own weight. It is also useful for comparison of sensibility to pin prick on two symmetrical places of the body. In this manner it is easier to achieve equal stimuli. The use of a pin is, however, preferable for determination of hypalgesic or analgesic boundaries on the small surfaces of the ends of the extremities.

This pinwheel has proved in many years' experience to be useful in the examination of skin reflexes, particularly the abdominal reflexes. In using a pin for this purpose or another sharp instrument, as was done before, painful scratches of the patient's skin often occur. I was often amazed to see how severely the skin of the patient's abdomen can be scratched when the doctor had been "struggling with abdominal reflexes" as my teacher Dr. Cassirer indignantly used to say. Another disadvantage of using a scratching motion for abdominal reflexes is that in this way a shaking of the abdominal wall may be produced which simulates a contraction of the abdominal muscles. Both disadvantages can be avoided by examination of the abdominal reflexes with a pinwheel, which is quickly rolled over the abdomen under light pressure. I have found frequently and very definitely that abdominal reflexes which could not be elicited by using a pin or a sharp instrument could be found clearly by use of the pinwheel. In the latest edition of his *Lehrbuch der Nervenkrankheiten*, Bing (1937) says in the discussion of hyporeflexia and areflexia abdominalis, page 171: "When weak stimuli fail, the abdominal reflexes can certainly be brought to light by the use of the 'pinwheel' recommended by Wartenberg."

THE RECURRENT (INFERIOR) LARYNGEAL NERVES

To the Editor—In THE JOURNAL, September 4, you published a communication from Dr John F Quinlan criticizing the following statement which appeared in your editorial (July 17) on total thyroidectomy for congestive heart failure "Injury to the recurrent laryngeal nerve was recorded in 82 per cent of the cases. In no instance was it bilateral or permanent." Contrary to his criticism, this simple and concrete statement of fact contains no "gross anatomic ambiguity" nor is there, "by implication, a definite falsehood." Moreover, the BNA does recognize the recurrent laryngeal nerve and gives it the simple Latin designation 'nervus recurrens'.

Furthermore, his assertion that "there is only one recurrent nerve in the body" is erroneous. There are two recurrent laryngeal nerves and also two recurrent mandibular and recurrent maxillary nerves to say nothing of the many other recurrent meningeal nerves.

According to Dr Quinlan, there is no right recurrent laryngeal nerve and he attempts to explain the asymmetry. This assertion is likewise false, since the right recurrent laryngeal nerve arises from the vagus and hooks around the subclavian artery (at the base of the neck) and ascends in the groove between the trachea and esophagus, to reach the larynx finally. Hence the right and the left recurrent nerves have practically the same course in the neck and thus have a similar relation to the thyroid gland and either may be injured in operations on this gland.

His final statement concerning "thoracic diseases involving the mediastinum—infections, growths, aneurysms" is irrelevant to your discussion of thyroidectomy. It is of course evident that only the left recurrent nerve—which hooks around the aorta—enters the thoracic cavity, since the right one hooks around the right subclavian artery, which lies above the thorax—in the neck.

INTESTINAL OBSTRUCTION FROM DRIED FRUIT

To the Editor—The report of a case of intestinal obstruction, caused by the ingestion of half of a dried peach, which, swallowed unchewed, passed undigested into the small intestine completely occluding the lumen of the bowel, is of great interest. This patient of Drs Andrews and Walker of Great Falls, Mont., (THE JOURNAL, August 7) is probably not an isolated case.

In the forenoon of April 25, 1934, I was called to see an obese edentulous woman, aged 70, who had had severe abdominal pains all through the night. Great distention, fecal vomiting, fever and a very rapid pulse made the diagnosis of intestinal obstruction imperative. She was admitted to the hospital and an attempt was made to improve her desperate condition, but she died in a few hours. Myocardial degeneration and chronic nephritis barred an operation and contributed to the outcome.

The postmortem examination disclosed a fusiform swelling at about the middle of the small intestine, which on being incised proved to be the two complete halves of large dried peaches, undigested and swollen again to their original fresh forms, lying one above the other and in contact, the convex surfaces turned in opposite directions, completely obstructing the bowel. These halves were firm, the indentation in the middle showing the perfect convolutions where the stone had been removed, and the skin was rather smooth and firm.

The patient had been stewing peaches the day before and, placing some dried pieces in her mouth merely moistened them with saliva, sucked them a bit and swallowed them unchewed, as she was not wearing her plates.

The lesson is plain: dried fruits unsoftened and unchewed cannot be swallowed with impunity. Even when chewed, a mass may form and cause trouble, but in view of the fact that large peaches are now dried, after being only halved, it is evident that they constitute a menace for those who might ingest them in the dried state, this is especially true in the case of children and the edentulous.

ALEXANDER NETTELROTH, M D, Louisville, Ky

JACKSON AND JAMES PAGET

To the Editor—It is pleasant to find this letter of James Jackson (1777-1867) addressed to Sir James Paget in the collection of the Royal College of Surgeons. Jackson is still remembered by his Letters to a Young Physician (1855) and his early scientific work on vaccination in the United States. The letter is revealing of his day and also shows that he never lost contact with the British medical world.

Boston 22 Sept 1855

Sir

I take the liberty of sending two books of which I beg your acceptance. If you will look into them you will find I am an old man. You will perceive deficiencies enough but you may perhaps perceive in me a love of what is true and beautiful in science. My principal object in forwarding you these books is to get an opportunity to express my feelings of respect to you. This I have been desirous to do for a year past—since reading your lectures on surgical pathology.

In reading these lectures I was constantly reminded of John Hunter. It seems to me that no one in these fifty odd years since his death has shown the same spirit in studying and interpreting nature as you have done. His love and close observation of nature were such that all his labours retain their value even on points where others with greater opportunities have gone far beyond him.

So far his fidelity is justified—his fidelity in observation. But in many instances may it be found that in looking closely at what he did see he anticipated what subsequent discoveries have confirmed. This could be shown to be more true than it would appear to be at first view if his language were correctly explained. For instance he spoke often of actions in different parts in such terms so that his readers have thought of some peculiar kinds of motion in the extreme aspect.

He then delivers a eulogy of Paget and hopes that he lives to make new conquests.

"Conquests which do not break down and destroy God's works, but of which the object is to remove the obstacles to a right interpretation of the works of creation—of the plans of the Deity and of the laws he has ordained."

R H HEINDEL, Philadelphia

CEVITAMIC ACID STIMULATION OF SPECIFIC ANTIBODY FORMATION

To the Editor—I have read with great interest the editorial on "Cevitamic Acid Stimulation of Specific Antibody Production" in THE JOURNAL, August 28. Unless I am mistaken, Dr Bernard L Oser and I were the first to report that cevitic acid, when administered in sufficient dosage, altered the immunologic responses in guinea-pigs. We demonstrated the fact that larger doses of cevitic acid reduced and inhibited the susceptibility of the guinea-pigs' skin to experimental sensitization with neoarsphenamine, and that the dose necessary to achieve this effect was higher than the minimal dose necessary to protect against scurvy. The publication by Oser and myself, which appeared in the *Proceedings of the Society for Experimental Biology and Medicine* (32:716 [Feb] 1934) is as far as I have been able to ascertain, the earliest report of experimental work dealing with the influence of cevitic acid on immunologic mechanisms. This report was amplified in our presentation before the thirteenth International Physiologic Congress at Leningrad in 1935. Our results have since been confirmed by Bruno Streitmann and Albert Wiedmann (*Arch f Dermat u Syph* 175:696 [July 6] 1937).

MARION B SULZBERGER, M D, New York

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT HOWEVER REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS BUT THESE WILL BE OMITTED ON REQUEST.

CEREBRAL VASCULAR SPASMS

To the Editor—Nov. 24 1936 a man aged 48 weighing 156 pounds (71 Kg) without coat or shoes and 5 feet 8½ inches (173 cm) in height was taken with numbness and tingling in the right side of the face which was followed by paralysis of the right side of the face. The paralysis did not affect the brow or the muscles around the eye the principle evidence of paralysis being around the angle of the mouth. Previous to this attack the patient had six or eight attacks of numbness in the right side of the face and in the thumb and the index and middle fingers of the right hand which affected speech if he was talking but were transitory and passed off within a minute or two leaving no paralysis. The blood pressure has varied from 130/98 to 124/87. The patient has a reddish bronze color of the face and back of the hands and is of the hypersensitive type with vasomotor instability. The pulse varies from 80 to 96 lying down. The basal metabolism was plus 27. Blood calcium was 11.2 mg per hundred cubic centimeters, blood urea 24 mg and blood sugar 127 mg. Hemoglobin was 95 per cent. Red blood cells numbered 4 750 000 white blood cells 10 500. The Wassermann reaction was negative. The urine showed a specific gravity of 1.026 a very faint trace of albumin and no sugar. Microscopic examination showed from 15 to 20 white blood cells to a high power field and no red blood cells. Expressed secretion from the prostate (in urine) showed 40 white blood cells to a high power field and 3 red blood cells the specific gravity being 1.022. Physical examination showed dilated veins in the fundi of the eyes. Deep and superficial reflexes were hyperactive and equal on the two sides. Abdominal reflexes were present and equal. No Romberg Babinski Oppenheim Chvostek's or Trousseau's sign was elicited. The pupils were equal and reacted to light and in accommodation. Flexion and extension of the limbs was normal. There was a slight sagging of the tissues around the right angle of the mouth. The patient could pucker the lips normally. The prostate was not enlarged. The heart lungs and abdomen were normal. There was slight enlargement of the left lobe of the thyroid. After five days the paralysis around the angle of the mouth had improved but weakness was apparent on talking and there was some speech defect. The patient's diet was questionable as it is thought it lacked citrus fruits green vegetables and fresh meats. One quart of milk was taken daily. It was thought that the patient's paralysis was due to a small leak in a blood vessel. Three dead or suspicious teeth were extracted. A preparation of theobromine and phenobarbital was ordered and I expect to try small doses of compound solution of iodine from 1 to 3 drops three times a day if advisable. A nap in the afternoon and a balanced diet were ordered with prostatic massage once every five days. Is this treatment suitable and ample? Is there danger in giving compound solution of iodine? Could this condition be due to functional derangement or to the toxic effect from the thyroid or an unbalanced diet? Do these infected prostates get well and stay well from massage? Would it be advisable to operate in such a thyroid case and if so how long after the attack? Would x-rays be preferable to surgery? Does recurrence of the numbness that preceded the attack of paralysis mean that bleeding continues? Does the increase in urea nitrogen with the rather high specific gravity justify protein restriction? What is the protein carbohydrate or fat content of powdered brewers' yeast? Please give suitable treatment for such a case and give the prognosis.

M D Virginia

ANSWER—Transient sensory or motor paralyses such as described are quite common, especially in the later decades of life and are usually attributable to cerebral vascular changes which are at first reversible but nearly always eventually become permanent. The theory that they are due to vascular spasm is widely but not unanimously held. Kinnier Wilson for instance suggests (*Brit M J* 1 487 [March 16] 1929) that they may be due to a temporary fall in systemic blood pressure which renders a partially sclerotic vessel unable for the time being to supply adequate amounts of blood. Arterial hypertension is frequently found in patients with such transient cerebral phenomena. In the case cited, though the blood pressure is not markedly elevated there are other suggestions of vascular disease in the blood urea and urinary observations. In addition it is stated that vasomotor instability was noted an observation consistent with the idea that the patient's cerebral symptoms are due to intermittent vascular changes. Such patients in most instances finally fall victim to cerebral thrombosis rather than to hemorrhage. Syphilis is sometimes a factor in producing these changes and should be further excluded by an examination of the spinal fluid.

A single basal metabolic rate estimation of plus 27 in the absence of other evidence of hyperthyroidism calls only for a repetition of the test and does not warrant the administration of iodine, especially at the age of 48, when it may indeed be dangerous. In the patient under discussion the blood pressure quoted makes hyperthyroidism unlikely.

In the treatment of such a patient the diet should be well balanced and slightly laxative, with an average protein content. Constipation should be treated by the use of lubricant if necessary, in order to avoid any straining at stool. Tobacco should be forbidden or greatly restricted, depending on the patient's existing degree of addiction. Strenuous exercise is to be avoided, as are excitement and emotional stress. Potassium iodide may be administered in doses of 0.65 Gm three times a day temporarily while the facial weakness persists. The bromine or similar compounds are indicated in moderate doses. The prognosis in the case cited is difficult to state without prolonged observation but should be regarded as dubious since most patients with such symptoms die of cerebral thrombosis within a few years. The patient should however, be spared the extra burden of such a gloomy outlook, although responsible relatives may well be warned.

A good grade of brewers' yeast contains about 46 per cent protein, 40 per cent carbohydrate and 2 per cent fat.

OSTEOCHONDRITIS OF FEMORAL EPIPHYSIS

To the Editor—A 3 year old girl had bloodless reduction of the hip in May 1936 with good results but the head of the femur shows (last 10 months) osteochondritis with a mottled head. What should be done in this condition?

L J SVETLIK M D Cleveland

ANSWER—Osteochondritis of the capital femoral epiphysis is seen not infrequently after the bloodless reduction of a congenital dislocation of the hip joint. It is probably due to the traumatism attendant on the manipulation. No pathologic evidence has been adduced to support the theory of diminished blood supply through injury to the artery in the ligamentum teres, but this theory seems at least as logical as any of the others.

The actual pathologic process is a softening of the trabeculae in the capital epiphysis. This softening extends in most cases into the metaphysis. The mottled appearance, sometimes called fragmentation, is due to retention of calcium in areas deprived of blood circulation.

The softened capital epiphysis becomes flattened and widened (mushroomed) under the influence of the body weight and muscle pull, and the entire head and neck of the femur become involved in a coxa vara deformity. The end result of this deforming process depends on the extent and severity of the softening and on the efficacy of the treatment. In some untreated cases the coxa vara becomes so marked that abduction of the thigh is impossible and other motions of the hip joint are definitely limited. The actual shortening may amount to more than an inch. In view of such possible end results it is highly desirable to institute the same treatment that is indicated in cases of ordinary Legg-Perthes osteochondritis juvenilis coxae.

The use of plaster-of-paris spica casts is not advisable, because circular plaster-of-paris casts tend to produce demineralization and softening of bone, and because the prevention of weight bearing on the softened femoral head is much more important than the prevention of motion in the hip joint.

For these reasons a simple Thomas knee splint (often erroneously called a hip splint) of the ordinary or of the caliper type should be carefully fitted to the affected leg. This splint should have a comfortably padded ring, covered with wash leather, and the uprights should be 1½ inches longer than the leg so that no weight can be borne on the foot. If there is any tendency to pain or sensitiveness in the hip joint, with spontaneous muscle spasm, a traction device such as the Boston windlass or a pair of wire loops should be provided at the foot of the splint, so that adhesive plaster traction may be utilized. The splint will have to be worn for perhaps a year, so it is well to have the uprights adjustable for extra length. A sole and heel 2 inches high should be applied to the shoe of the opposite foot, and the child can then be allowed to walk freely. The splint must be worn at night as well as in the daytime. Complete rest in bed with a Bucks extension on the affected leg has been highly recommended by Danforth and others but is hardly advisable in the average case.

X-ray examinations should be made every two or three months to ascertain the rate of progress.

Calcium and phosphorus in some form and cod liver oil or one of the ergosterol or viosterol combinations should be administered with intelligence. Actual or artificial sunlight is to be recommended together with the application of local heat.

The objectives to be sought therefore, are to prevent deforming pressure on the softened head of the femur and to aid the recalcification and hardening of the bony structure.

In a child of 3 it would not be wise to consider drilling the femur into the neck and head of the femur by way of the trochanter.

HISTAMINE TEST OF CAPILLARY CIRCULATION

To the Editor—Is the skin test for deficiency of arterial circulation of 1,000 solution of histamine acid phosphate in physiologic solution of sodium chloride accurate and efficient? Is it reliable in every case? This is advocated by Geza de Takats in the *Archives of Surgery* 18: 671 [Feb.] 1929) wherein he cites Thomas Lewis's *The Blood Vessels of the Human Skin and Their Responses* London, Shaw and Sons 1927

M D, Iowa

ANSWER—The accuracy and efficiency of any biologic test procedure are dependent on the intelligence of the interpretation. The histamine flare test is physiologically sound and clinically useful in studying the capillary circulation, but to say that this or any other test is "reliable in every case" is unjustified. With the infinite variability of biologic constitution and response, errors due to misinterpretation can, do and will occur. The well known dictum that laboratory and other tests must not be blindly accepted in the face of contrary direct clinical evidence is still most true.

Lewis showed that a "triple response" occurs on the injection of minute quantities of histamine into the skin. In about twenty seconds a small red spot develops immediately about the puncture. Shortly afterward a widening red flare appears and after one or two minutes a small wheal appears exactly covering the red spot. The local red spot (first response) is due to capillary and venule dilatation and this occurs also in denervated skin. The secondary response of flare is due to arteriolar dilatation and local active hyperemia. The formation of the edematous wheal is dependent on locally increased blood flow and injury to the capillary endothelium, so that it becomes permeable to blood plasma. In view of the minute size of the vessels involved in this sharply localized reaction, one must interpret the character of the response as indicative of the condition of the capillaries, venules and precapillary arterioles only. It is not justified to consider these reactions as involving the larger arterial branches. Thus the test is by no means ideal for determining the rate or extent of blood flow in larger arteries for response will occur even with only a poor arterial supply of blood.

GLOSSODYNIA

To the Editor—I have a patient who complains of a sensitive tongue. He is a white man, aged 40 and is in good health otherwise. His tongue appears normal to inspection and his teeth and gums are in good condition. There are no sharp edges to irritate the tongue. The condition has been present for four years. He has remissions and exacerbations of the disease. He states that the tongue feels scalded as if from drinking something too hot. Hot foods and highly seasoned foods make the pain worse. Smoking seems to make the condition worse and he has omitted tobacco for months at a time but still has the trouble. The pain is located on the tip and sides of the tongue. His nose and throat are normal. Gastric analysis gives normal results. He does not have indigestion. There is no cardiorespiratory disease. There are no allergic symptoms. The Wassermann reaction is negative. The red and white blood cell count is normal. I have diagnosed this as chronic superficial glossitis. Do you think this diagnosis is correct? If so what is the treatment of this condition? What can be expected from the treatment that is can he get a permanent cure? Kindly omit name and town.

M D Louisiana

ANSWER—The diagnosis should be glossodynia rather than glossitis, for the description mentions no sign of inflammation of the tongue. Glossodynia may be due to (1) ill fitting dentures pressing on the anterior and posterior palatine foramina (2) disturbance of the temporomaxillary joint by an abnormal bite (3) sensitization to artificial dentures, (4) unclean fissures in a scrotal or lymphangiomatous tongue, (5) electric currents between metal dentures, (6) disease of the lingual tonsil (7) avitaminosis, (8) pernicious anemia or (9) idiopathic glossodynia. Only causes 5 to 9 need be considered in this case.

5 I am in 1932 called attention to the presence in many mouths of small electric currents, which in some instances cause pain or even erosions of the mucous membranes. They can be stopped by replacing tooth fillings so that all will be of the same metal. (Lain, E S. Chemical and Electrolytic Lesions of the Mouth Caused by Artificial Dentures. *Arch Dermat & Syph* 25: 21 [Jan.] 1932, Electrogalvanic Lesions of the Oral Cavity by Metallic Dentures, *THE JOURNAL* March 11, 1933 p 717)

6 Sluder in 1918 described the effects of disease of the lingual tonsil. Pain at or near the tip of the tongue is one of those effects. (Sluder, Greenfield. Some Clinical Observations on the Lingual Tonsil Concerning Goiter, Glossodynia and Focal Infection, *Am J M Sc* 156: 248 [Aug.] 1918)

7 Avitaminosis possibly related to pernicious anemia is sometimes responsible for pain in the tongue. (Hutter, A M,

Middleton, W S, and Steenbock, Harry. Vitamin B Deficiency and the Atrophic Tongue, *THE JOURNAL*, Oct 21 1933, p 1305)

8 Pernicious anemia often causes pain in the tongue even before the blood or stomach signs have appeared or there is any inflammation of the tongue. The case under discussion, if no other cause of the trouble has been found, should be watched with this possibility in mind.

The pressure of tumors or an inflammatory neuritis may cause glossodynia in rare cases. Cancerphobia has something to do with some cases, though it is often a result of the pain rather than a cause of it. Discovery of a cause amenable to treatment makes a good prognosis.

9 There are cases, however, in which the cause remains hidden. For these palliation is the only possible line of treatment and this is usually unsatisfactory, for anesthesia destroys the sense of taste. It may be attempted by having the patient hold Dobell's solution in the mouth for several minutes or by the use of ethylaminobenzoate.

HEART ATTACKS AND INDIGESTION

To the Editor—A married woman aged 60 has had frequent attacks of indigestion for the past year or so most of which occurred when she had gone to New York (a short train ride relationship presumably associated with exertion). Attacks are characterized by epigastric distress, gas and occasionally nausea. She has had no medical attention for many years because aside from this she has been in unusually good health. The present attack is similar to the others but much more severe. The duration when first seen was about four hours. Onset had been rapid but not sudden. The chief complaint was a severe constant epigastric pain not referred to either side of the abdomen. Nausea was present and the patient had vomited three or four times. There were moderate gaseous eructations. The bowels were normal. There were no other complaints. The patient was obese and when examined, in acute discomfort from pain. There was no dyspnea or cyanosis and no evidence of shock. Vomiting occasionally occurred. The heart was moderately enlarged to the left to percussion the sounds were of poor quality. There was a generalized precordial systolic murmur. Frequent extrasystoles (often four or five in a row) occurred. The apex rate was 96. The radial pulse was 80 and of extremely poor quality. The blood pressure was 140 systolic 100 diastolic. The lungs were clear. The abdomen was not distended and was without spasm or masses. There was very slight generalized tenderness. No clubbing or edema of the extremities was present. She was given digitalis and the hydrochlorides of the alkaloids of opium principally morphine. The following morning (twelve hours later) the patient felt slightly better. She had vomited several times during the night. The pain had shifted to the right lower quadrant although a mild epigastric distress remained. The tongue was dry. The pulse was of excellent quality and regular with a rate of 80. There was no pulse deficit and only occasional extrasystoles occurred. The oral temperature was 99.6 F. The rate of respiration was 24. The blood pressure was 160 systolic 84 diastolic. The patient had a total of 7½ grains (0.5 Gm.) of digitalis. The heart sounds were much improved. The chest was clear the murmur unchanged. The abdomen was soft with slight tenderness at McBurney's point. Pelvic and rectal examinations were negative. An electrocardiogram taken at this time showed iso electric T₁ and low T₂ and T₃ with definite evidence of coronary sclerosis but not of any infarct. No irregularity was present. Seven hours later the pain in the right lower quadrant had subsided somewhat and the patient was considerably more comfortable. A low saline enema had given good results and some flatus. The rectal temperature was 102.6 F. The abdomen was slightly distended. Peristalsis was overactive. Tenderness at McBurney's point was marked. Pelvic and rectal examinations were still negative. The leukocyte count was 17,250 with 85 per cent polymorphonuclears and a shift to the left. A diagnosis of acute appendicitis was made, and appendectomy was done under tribrom ethanol gas-oxygen anesthesia. The appendix was found bound down with old and recent adhesions in a fatty bed. The tip and the base were both gangrenous the latter being the site of a fecalith. There was a small amount of free seropurulent exudate. The appendix was removed with out rupture and the abdomen was drained. It is not probable that the heart condition is secondary to that of the appendix. What is the most likely cardiac diagnosis? What is the prognosis regarding future coronary thrombosis in the light of the present illness?

M D New York

ANSWER—With a woman of 60 with coronary disease it would seem as if attacks of indigestion which come particularly when she overexerts herself on trips to the city should be ascribed to cardiac embarrassment. The fact that before this illness she enjoyed good health tends to rule out cholecystitis and other common causes of indigestion.

Care must be exercised in making a diagnosis from abnormal T waves when large doses of digitalis have recently been given. Another electrocardiogram should be studied later. An exact diagnosis with regard to the heart condition can hardly be made on the basis of the facts now available. It is doubtful whether the heart trouble is due to the appendicitis. If the patient has had a coronary thrombosis, the prognosis will depend largely on the amount of cardiac reserve which the patient has when she gets up and starts to walk again. If her rope is then short—in other words, if when she starts to walk she is soon halted by distress or precordial pain or dyspnea—the prog-

nosis will be poor. If, however, she finds after a good rest and complete recovery from the appendicitis that her cardiac reserve is large it may well be that she will go on to live in fair comfort for years.

TREATMENT OF DIABETES

To the Editor—A man aged 65 weighing 171 pounds (78 kg.) and 5 feet 10 inches (178 cm.) in height has had diabetes for fifteen or twenty years and his tolerance to insulin seems to be gradually increasing. His diet at present is carbohydrate 142 Gm, protein 86 Gm, fat 120 Gm divided as follows:

	Carbo- hydrate Gm	Protein Gm	Fat Gm
Breakfast	48	26	64
Lunch	39	13	18
Supper	55	47	38

Twenty minutes before breakfast he receives 75 units of insulin and twenty minutes before supper 40 units. He has taken this dosage for the past six months and never had an insulin reaction. Sugar is present almost constantly in the urine. The last fractional test showed from 7 to 11 a m 4 plus from 11 a m to 4 p m 1 plus from 4 to 9 p m 2 plus and from 9 p m to 7 a m a trace. He has urinary frequency of moderate severity but no thirst. He complains of pains in the legs and shows slight impairment of tactile discrimination on the feet. The dorsalis pedis pulsations are good. Six months ago he was taking about 75 units daily without satisfaction so he entered a hospital for ten days and was never satisfactorily regulated, leaving the hospital with his present dosage. No infection is present. The urine usually shows a trace of acetone. The blood sugar stays between 300 and 400. The patient is doing office work and feels fairly well except for the pains in his legs. Attempts to reduce his caloric intake six months ago made him feel weak. Please offer suggestions for treating this case.

J. CAMPBELL KERN, M.D., Sanderson, Texas

ANSWER—If the persistent blood sugar values of 300-400 mg per hundred cubic centimeters are morning fasting blood sugars, the fact that the patient's 9 p m to 7 a m urine specimen shows only a trace of sugar means that he must have a steeply rising blood sugar at about 6 a m. It is difficult to keep this type of patient completely sugar free on any dosage of ordinary insulin. The newly available protamine zinc insulin makes it possible to control this type of case much more adequately. Protamine insulin might be tried in approximately the same doses as the regular insulin now used but administered one hour before breakfast and supper respectively. Giving the total dosage of protamine insulin in one dose in the morning, is not recommended for this type of patient.

Because of the patient's age, because of constant presence of a trace of acetone in the urine, and because the attempt at reducing his caloric intake made him feel weak, it might be well to increase the carbohydrate content of the diet, for instance, carbohydrate 187 Gm, protein 86 Gm, fat 100 Gm.

If for any reason it is not desired to change the type of insulin used, the morning dose of regular insulin may be cautiously increased (about 5 units at a time) until fractional urine tests show that the urine is almost free from sugar throughout the day. During this time it may be necessary to reduce the evening dose of insulin somewhat, in order to avoid hypoglycemic reactions during the evening or early morning hours. Having obtained better control of the diabetes as shown by the urine tests, one can then obtain a more exact idea of the adequacy of the control by determining the blood sugar values not only in the morning before breakfast but also at appropriate intervals during the day. It would be better not to start this suggested change in insulin dosage until the effect of the change in diet has been observed.

BILE SALTS FOR ARTHRITIS

To the Editor—What is the present status of bilirubin and bile salts intravenously in the treatment of infectious arthritis? M.D., Arizona

ANSWER—Researches on the effect of injections of bilirubin and bile salts in cases of chronic infectious (atrophic) arthritis have been begun but recently. Only a preliminary report of them has been made (*Science News Letter*, June 19, 1937) and this form of treatment is still distinctly an investigative procedure. Bilirubin is still quite expensive; the method of preparation of the bilirubin bile salt mixture is empirical and the solutions which must be prepared daily are not stable. Hence it is not yet a procedure for general use. This method of research therapy was reported by Thompson and Wyatt of Tucson, Ariz., at the Atlantic City meeting of the American Rheumatism Association, June 7. Ten patients with chronic atrophic arthritis were given daily intravenous injections of the bilirubin-bile salt mixture for about eight to twelve days. It was reported that artificial hyperbilirubinemia was accomplished and that remissions in symptoms of the arthritis were

induced for variable periods. In some cases symptoms recurred after two or three weeks, in other cases they had not returned after five months. Hench observed that when patients developed a significant intercurrent jaundice (with a serum bilirubin more than approximately 8 to 10 mg per hundred cubic centimeters) a prompt and dramatic remission in symptoms was induced. At the recent meeting Hench reported further observations on the phenomenon as it affected a second series of thirty-one patients with atrophic arthritis, fibrositis or sciatic pain. All the fibrositic patients and 63 per cent of the arthritic patients were relieved temporarily of all rheumatic symptoms. Thirty-seven per cent of the arthritic patients were markedly but incompletely relieved. The remissions lasted from three weeks to forty-five months, in general they lasted several weeks. The arthritic patients were relieved of symptoms for an average of about four months, the fibrositic patients for an average of about five months. In the majority of cases the rheumatic symptoms returned to their previous intensity, but in 39 per cent the symptoms returned (and remained) in milder form. The effect of jaundice is more quantitative than qualitative since several types were equally effective in precipitating the phenomenon: intrahepatic jaundice from cinchophen, spontaneous intrahepatic jaundice of the catarrhal or epidemic "infectious" type, jaundice associated with hepatitis and cirrhosis, obstructive jaundice from stones or a malignant condition. The phenomenon seemed to be relatively specific for atrophic arthritis and fibrositis. The pains of acute gouty arthritis, postherpetic neuralgia, ischemic neuritis, parietal metastasis and arthralgia of a special type were unrelieved in the presence of jaundice.

The therapeutic implications were obvious and Hench tried to repeat the phenomenon by the use of bile salts, bile feedings by stomach tube, transfusions of jaundiced blood and experimental jaundice from toluylenediamine. He concluded that chronic atrophic arthritis and primary fibrositis are not necessarily relentless, uncontrollable diseases. Nature apparently possesses a highly effective method of producing a dramatic remission, this phenomenon is precipitated more rapidly and completely by jaundice than by any other known physiologic change or therapeutic method.

If the method of Thompson and Wyatt can be repeated successfully it will permit clinical investigators to study the phenomenon much more closely and perhaps help them to isolate the responsible agent and utilize it for the future treatment of chronic arthritis.

CLIMATE IN PULMONARY TUBERCULOSIS

To the Editor—Would you kindly tell me whether the climate of Santa Fe, N. M. or Colorado Springs is considered better for a patient with an early pulmonary tuberculosis?

W. E. DELICATE, M.D., Edwardsville, Ill.

ANSWER—There is considerable diversity of opinion regarding the value of climate and altitude in the treatment of pulmonary tuberculosis. If one were to accumulate pamphlets from chambers of commerce of twenty-five cities that enjoy reputations as health resorts, one would find in each pamphlet apparently convincing arguments as to just why that particular location is best for the tuberculous patient, and yet the climatic conditions would vary greatly and the altitude would range from approximately sea level to 7,000 feet or higher. After all, the treatment of pulmonary tuberculosis has been pretty well standardized by physicians, essentially the same methods are practiced in all parts of this country and other nations.

The most important step in the treatment of any patient with tuberculosis is to make sure that he is under the care of a well qualified physician who will recommend and carry out the various therapeutic measures as they are indicated and will provide for adequate nursing care when necessary. Mainly because of the large number of tuberculous patients who have been migrating to the southwestern part of the United States during the past few decades there has been a demand for physicians highly trained and experienced in tuberculosis, with the result that there is now located in every city one or more first class physicians in this field. This holds true of both Santa Fe and Colorado Springs. Therefore either place would be satisfactory, provided the patient selects or is referred to a first class physician and is pleased with his surroundings. The climatic condition should be looked on as a minor consideration.

SYSTEMIC REACTIONS TO QUININE

To the Editor—I wish to ask a question regarding certain symptoms that appeared after an injection of quinine. A woman aged 36 in good general health received three injections of quinine and urethane (5 grains or 0.3 Gm) for varicose veins. The first two were followed by no reaction other than a mild generalized burning and tingling sensation. The third injection was followed by a more severe reaction: the generalized burning and tingling were much worse and in addition there was a pronounced bitter quinine taste in the mouth. The injection was given at 8 p. m. and the bitter taste lasted the rest of the evening. Because this injection was into a large vein in the thigh the patient was under the impression that more of the quinine spilled over into the system than was the case with the first two injections. The morning after the third injection the patient felt well. At 2 p. m. without warning there was marked blurring of vision of the left eye (she tested each eye separately) tingling of the left side of the face in the region of the eye and a dull ache in the left frontal region. She was alarmed and lay down between 2:30 and 3 she fell asleep. At 5 o'clock when she awoke she was well and the symptoms did not return. At the age of 12 she was confused for a few hours after taking quinine for a cold but throughout her subsequent life she habitually took 5 grains of quinine for a cold without abnormal effect. She is not sensitive to other drugs. Neither she nor any of her family has ever had migraine. Are symptoms like hers known to occur after quinine and urethane and are they a contraindication to further treatment? Please omit name.

M. D. Pennsylvania

ANSWER—Untoward systemic reactions following the intravenous injection of quinine may be grouped into immediate and delayed reactions. They may be caused by sensitivity to the drug which manifests itself in edema, cyanosis and bronchial spasm and may give an alarming picture unless promptly aborted by epinephrine. The late reaction is seen from six to ten days later as a generalized itchy eruption, malaise and fever, and it may last several weeks. The description of the correspondent, however, suggests a toxic reaction to quinine. It is known that certain patients respond to moderate doses of quinine with dizziness and with visual and aural disturbances. Their central nervous system is intolerant to the drug. Once such a reaction is obtained, it is unwise to proceed with the drug as subsequent doses may have a cumulative effect. It must be remembered that approximately one out of every 200 patients will show some intolerance to quinine. Therefore it is advisable to start with small doses such as 1 cc. of a 10 per cent solution (0.1 Gm, or 1½ grains). The initial dose of 5 grains seems high.

One might conceive finally that the unilateral tingling pain and blurring of vision occurred on a vascular basis by embolism or vascular spasm of the cerebral vessels. Certainly with these antecedents the further use of quinine would not be advisable. One can switch to 10 per cent sodium morrhuate or 10 per cent potassium oleate, but even these drugs should be given in small initial doses and in not longer intervals than five days apart to minimize sensitization.

TREATMENT OF SYPHILIS

To the Editor—In March 1934 I saw a white woman aged 23 with some half dozen deep ulcerations about the face. There were also numerous white irregular scars from previous ulcers that had healed. The history revealed the presence of these for eighteen months. A blood Wassermann reaction showed four plus. A diagnosis of syphilis with tubercular syphilitic lesions of the face was made. The patient gave no history of syphilitic infection. However the husband admitted a syphilitic infection of some six years standing. Under antisypilitic treatment both local and systemic these lesions healed and the patient's general condition improved. The patient had thirty five doses of neoarsphenamine (from 0.6 to 0.75 Gm each) and thirty five doses of a bismuth compound during the following fifteen months with rest periods interspersing the courses of each drug. There has been no treatment since the middle of 1935. A Wassermann test at that time still showed a four plus reaction. The patient was symptom free. Will you tell me through your columns what treatment if any you would recommend for this patient?

M. D. Iowa

ANSWER—Unfortunately the correspondent does not give enough information to judge the condition of the patient accurately. Apparently there has been no change in the blood Wassermann reaction throughout the treatment. On the other hand no statement is made whether the physical examination shows any evidence of central nervous system involvement. It is most essential that a lumbar puncture be done in a case of this sort, for that may go far to explain the persistently positive Wassermann reaction. It is not uncommon for a patient who has had syphilis of some years duration to have a persistently positive Wassermann reaction. Also no mention is made of the possibility of involvement of the cardiovascular apparatus which might explain a persistently positive Wassermann reaction. We would recommend that the patient be gone over carefully from this point of view. If this is done and no evidence of involvement is found one must simply look on the patient now as having recovered at least from her ulcerocrustaceous

sypyloderm. The cooperative group studies have shown without any question that far better results are achieved when alternating courses of arsenicals and bismuth compounds are given without any rest periods.

Under the circumstances we would recommend that the patient be given, provided there is no cardiovascular or central nervous system involvement, a course of weekly injections of mapharsen, each 40 mg and consisting of ten injections. This is to be followed by a course of weekly injections intramuscularly of bismuth salicylate, each equivalent to 0.13 Gm of metallic bismuth. Since the patient is now approaching the so called late period of the disease it might be perfectly safe after this further therapy to give her a rest period for two months and thereafter for two years to give her a course of ten intramuscular injections of a bismuth compound. Naturally such a patient should be kept under observation and gone over carefully every six months.

SWELLING AND DISCOLORATION NOT SIGNS OF DEATH FROM FREEZING

To the Editor—Recently in an adjoining county the wife of a rancher left her home about dusk, or shortly after dark and set out for an adjoining ranch during a severe subzero storm. Making little headway against the cold in the direction of her destination it appears that she retraced her steps and set out toward another destination so as not to have to face the storm. Two days later searchers found her frozen body in a ravine or other rough country, her legs exposed by her stockings being cut to ribbons by sagebrush through which she must have gone in the night. She was poorly clad in relation to the weather. Further it is reported by those interested in her affairs that when the body was thawed out to permit the undertaker's embalming the lips were extremely swelled and that the neck and face were much swelled and discolored, also that the undertaker could not embalm the head because of the ruptured condition of the vessels in this region. Thus the body was not given publicly at the funeral. The claim is made that there were many quarrels in the family and that on this occasion the woman left the house following such an altercation. At least it is presumed that she was roughly handled and that the condition of the face and neck was due to injury inflicted in the affair by the husband. A legal investigation has been initiated. I am informed. The question that is troubling relatives and others is whether these conditions were natural in a frozen body or whether they had a traumatic origin before the person was frozen or other parts of the body did not show such conditions. Not having seen a body exposed to such severe cold I could not give a positive opinion to my consultants. What would be the normal and the pathologic conditions? No claim was advanced that the woman encountered any severe traumatic injury after leaving her home or that she was lost in the storm but it is stated that she was subject to fits. To say the least the situation is controversial from any angle. PAUL P. HALLECK, M.D. Broadus, Mont.

ANSWER—The question is whether extreme swelling of the lips, face and neck with discoloration could have been caused by freezing of the body. The answer is no. The process of freezing itself does not cause any swelling and discoloration of the soft parts. The swelling and discoloration as well as possible rupture of the vessels in the neck must have been present before freezing took place. In cases like this it would be impossible to reach a satisfactory conclusion in regard to the nature of the swelling and discoloration without a thorough postmortem examination and determination of the condition of the bones and internal organs.

EFFECTS OF PHOSPHATURIA

To the Editor—A man aged 24 is apparently in perfect health except for a chronic phosphaturia with occasional dull pains at the end of the penis. He has had no venereal disease and other than an appendectomy two years ago the history is negative. Please advise me as to the cause, significance and treatment for this trouble.

STANLEY M. GATES, M.D. Monticello, Ark.

ANSWER—Normally the kidneys secrete from 1 to 5 Gm daily of phosphoric acid in the form of phosphates. The phosphates are in combination with the alkali bases (sodium, potassium, ammonium) or the alkaline earth metals (calcium, magnesium). At times the amount rises or the phosphates are precipitated by a change in reaction of the urine toward the alkaline. The calcium and magnesium phosphates are precipitated in alkaline urine.

The phosphates in the urine are derived partly from the food partly from the decomposition of organic substances containing phosphorus. They are increased in diabetes mellitus, bone diseases and pulmonary tuberculosis. They are especially abundant in the urine because of precipitation in chronic cystitis when an alkaline putrefaction takes place in the bladder. They are increased by a milk diet and by alkaline mineral waters. Muscular activity increases the excretion of phosphorus. A high purine diet increases uric acid and phosphorus excretion. The phosphates are markedly increased in cystic bone disease owing

to hyperfunction of the parathyroids Vitamin D administration and ultraviolet rays increase the phosphate excretion In rare cases there is a continued increase in the total amount of phosphates in the urine in the absence of disease, called true phosphaturia

A diagnosis of phosphaturia is usually based on the presence in the urine of a dense deposit of phosphates Analyses in many cases do not show an increased amount of phosphoric acid but merely a change in the reaction of the urine from acid to alkaline The phosphates precipitating in the urine are often secondary formations, which give rise to symptoms of pain or burning in the urinary tract similar to those of oxaluria

The treatment should remove any infection present, lower the intake of calcium and render the urine acid with acid sodium phosphate or ammonium chloride The fluid intake should be increased A balanced diet will often rectify the trouble in a short time

DIAGNOSIS OF SYPHILIS

To the Editor—A man aged 62 weighing over 200 pounds (90 kg) has led a strenuous business life for the past twenty five or thirty years In early manhood, following an acute disease, he had phlegmasia alba dolens Since that time his leg has remained swollen but has not given him a great amount of trouble About thirty years ago he had gonorrhea and following that some hypertrophy of the prostate This condition has not affected his virility nor could it be called a pathologic condition at this time During the past few years on three widely separated occasions he has had a blister like sore on the penis but it disappeared on the use of a mercury bichloride solution However when this sore appeared for the third time it was after a suspicious intercourse and a darkfield examination was made and showed no spirochetes However regardless of this and though it was too early for a Wassermann test to be of value he insisted on taking neoarsphenamine At his request he was given every other day three intravenous injections of 0.03 0.04 and 0.06 Gm of neoarsphenamine Within a day or two following this he had occasion to have his blood pressure taken and the systolic reading was 250 The next day it was 180 and now it remains at 170 Several weeks prior to the intravenous medication his blood pressure was 170 Would this rather rapid giving of an arsenical result in a temporary increase of blood pressure? The diastolic reading is not known There is apparently no kidney involvement At no time has the patient used alcohol to excess Occasionally he takes one or two highballs at night but does not make a practice of overeating As you see, the history of syphilis is rather vague and in my opinion the penile sores could not have been syphilitic He has also been a rather heavy eater

STANLEY M GATES, MD Monticello Ark.

ANSWER—One is never justified in starting treatment for syphilis without an absolute diagnosis One negative darkfield does not exclude a diagnosis of syphilis Repeated darkfield examinations should be made If they are negative, the patient should be followed with weekly Wassermann tests until such a time when one could be positive one way or another as to whether the patient has syphilis Sometimes with patients like this it is possible to make examination of the lymph node juices by puncture with a needle and do a darkfield examination on these fluids Consequently one is not justified in giving neoarsphenamine Moreover, a man 62 years of age, weighing more than 200 pounds, would not be a good subject for neoarsphenamine every other day It is not surprising that his blood pressure went up to 250

It is recommended that no more neoarsphenamine be used on this patient, but that a Wassermann test be made once a month for the next year If all of them remain negative, the chances are that he never did have a syphilitic infection

CRUDE PETROLEUM FOR ABRASIONS

To the Editor—What benefits may arise from the use of crude petroleum as a dressing for cuts particularly cuts and scratches on domestic animals? Has it any antibacterial effect and will it aid healing? Also has it any antiparasitic effect?

MD Iowa

ANSWER—Crude petroleum varies in composition, depending on its source Some areas, for instance, yield a product with a much higher content of sulfur than others There is likewise a considerable variation in their content of various toxic materials All samples have more or less toxicity It is therefore inadvisable to employ crude petroleum to any considerable extent as an application for wounds Furthermore, there have been no responsible reports describing any particular benefits from it for this purpose nor are there reliable studies showing any virtues for crude petroleum as a bacteriostatic On the contrary, what meager evidence there is seems to show that bacteria are not harmed by it Crude petroleum has been used to some extent as a parasiticide When infestations occur on man or animals however, it would seem better to use agents of a more uniform composition, less toxic action, and more certain parasitocidal effect

POSSIBLE HARM TO X-RAY OPERATOR DURING FLUOROSCOPY

To the Editor—I use the fluoroscope frequently For protection I use a medium weight apron and gloves but no head protection Often after fluoroscopy my face feels burned and the nose and throat feel dry and irritated At times also the skin of my body and legs feels irritated I also may feel tired and develop intestinal disorders Would you advise wearing the heaviest obtainable apron and gloves? Would you advise a head protection? Could the rays affect the thyroid gland and be responsible for an increase in weight?

MD New Jersey

ANSWER—From the description it seems that the protective measures used are safe Most of the manifestations described are probably not attributable to x-ray exposure, but it is better to be cautious than sorry, for the x-rays are subtle It is advisable to keep the kilovoltage below 85, not use more than 3 milliamperes, keep the aperture of the diaphragm as narrow as possible, test the protective glass of the fluoroscopic screen and not do fluoroscopy over prolonged and continuous period Incidentally, vertical fluoroscopy gives some protection because of the interposed patient Probably a head protector is not needed Also it is improbable that the increase in weight is due to x-ray exposure

POSITIVE WASSERMANN TEST IN UNRESOLVED PNEUMONIA

To the Editor—In the past year I have observed in our ward service a clinical syndrome commonly known as unresolved pneumonia (x-ray diagnosis) with positive syphilitic serologic reaction Does unresolved pneumonia produce a false serologic picture or does a weakly positive blood predispose to failure in pneumonic resolution? These patients show no clinical evidence of syphilis

J F LOEBLE MD Lebanon Pa

ANSWER—A positive Wassermann or Kahn reaction is some times observed during pneumococcal consolidation especially during the febrile period in patients who are not syphilitic A failure of pneumonia to resolve does not depend on the presence of previous syphilitic infection A weakly positive blood, under the circumstances narrated, is not evidence that the failure to resolve is due to a previous latent syphilis Alleged failure to resolve is often due to a preexisting tuberculosis, to a neoplasm or to preexistent bronchiectasis

TREATMENT OF ALCOHOLIC HANGOVER

To the Editor—What is your opinion on the treatment of post alcoholic hangover I have found nothing very effective in the treatment of the malaise and anorexia associated with the condition My patients are farmers who go on occasional or periodic sprees for a few hours at night and have to work the next day I realize that the best thing is the avoidance of excess but that is a big order for the people in this section Will you help me out?

MD Mississippi

ANSWER—The rational treatment for alcoholic hangover is suggested by the observations of Himwich and his associates (The Metabolism of Alcohol, THE JOURNAL, March 4, 1933 p 651) They showed that the ingestion of large amounts of alcohol causes retention of carbon dioxide and accumulation of lactic acid The treatment, therefore, should be directed toward the acidosis

INTRADERMAL USE OF VACCINES

To the Editor—Is there any advantage in giving vaccines intradermally as opposed to subcutaneously? If given intradermally should the same dosage or a smaller dosage be given? I have been told that vaccines given intradermally are more effective because the absorption is slower Is this true?

FRED S TABER MD New Brunswick N J

ANSWER—It is better to give vaccines intradermally rather than subcutaneously for several reasons Should an abscess develop, the subcutaneous injection will result in a much more extensive suppuration than would occur in an intracutaneous injection A small dose given intradermally is believed to give as good results as a larger dose given subcutaneously, because the skin itself is credited with specific immunizing qualities that are lacking in subcutaneous tissue As absorption is slower, there is less likelihood of a severe septic reaction after intradermal than after subcutaneous injections

ORCHITIS FROM UNDIANT FEVER

To the Editor—In Queries and Minor Notes in THE JOURNAL July 24 a question is asked by MD Georgia as to the cause of orchitis In reply brucellosis is not mentioned as a possible cause of orchitis although it is a well proved fact From my own experience I would say it is a rare complication of brucellosis (two in farces more than 200 cases) but nevertheless it merits worthy of special mention

Book Notices

Maternal Care. The Principles of Antepartum Intrapartum and Postpartum Care for the Practitioner of Obstetrics. Approved by The American Committee on Maternal Welfare Inc. Prepared by Dr W C Danforth Dr G W Kosmak Dr R L DeNormandle and Dr F L Adair. Dr F L Adair editor. Cloth Price \$1 Paper Price 25 cents Pp 93 Chicago University of Chicago Press 1937

This booklet should be studied most carefully by every practitioner of medicine who takes care of maternity cases, because it contains a wealth of useful information. It is safe to say that if a majority of the general practitioners in this country will acquaint themselves with the contents of this book there will be a marked improvement in antepartum, intrapartum and postpartum care with a consequent sudden and dramatic decrease in the maternal and fetal mortality and morbidity. The section on intrapartum care is particularly noteworthy for the general practitioner because it contains detailed instructions concerning the delivery of women in their own homes. Information is given not only for spontaneous deliveries but also for forceps operations, version and extraction, and breech delivery. The book is extremely well written and is delightful to read. The editor and his associates deserve the highest praise for their accomplishment.

Traité de biocolloïdogie Tome IV État colloïdal et biologie Fascicule VI Narcose Par W Kopaczewski Paper Price, 35 francs Pp 763 924 Paris Gauthier Villars 1936

This is the sixth (and completing) section of the fourth volume of Kopaczewski's 2,500 page work on the biocolloids. Such a treatise promises small reward to any publisher courageous enough to undertake it, wherefore thanks to France. In essence, this work is (as it must be) a "review." As such it recommends itself to any beginning worker too lazy to familiarize himself directly with first publications. But Kopaczewski's treatise brings a second good feature: it is critical. Half of this fascicle (pp 847-924) is devoted to author, subject, figure and table indexes (the last two interesting because unusual), the remaining half (pp 763 845) to a discussion of narcosis. The first pages of the second half discuss history—the discovery of the narcotics, their widely differing chemical (they may be organic or inorganic) and physical character (faradization and cold), and the universality of the narcotic response (all cells may be thus poisoned). There are tables covering the sensitiveness of different tissues to a given "anesthetic" and its relative concentrations in them, to the diffusion rates of the different narcotics and their final (equilibrium) concentrations. Interesting notes are made of antagonisms and synergisms existing between "anesthetics" and other compounds (caffeine, camphor, epinephrine or the acids). Correlations are cited between narcosis and the chemical constitution of the narcotics, their diffusion rates, their fat solubility, their surface activity and their colloid effects. Thus introduces a discussion of the existent theories of the process. Kopaczewski sums them up under seven heads. Beginning (in 1902) with the asphyxial theory of Verworn (which the author says belongs to Winterstein) he passes to that of Overton and Meyer, according to whom narcotic effect is the product of the coefficient of partition between an aqueous and a lipid phase. Traube's surface tension theory (attributed by Kopaczewski to Richardson, 1869) comes next, and fourth is recited Claude Bernard's coagulation hypothesis of 1875. The fifth item is made of the unrecognized view of Dubois (1884) that narcosis parallels dehydration and

the conversion of hydrophilic cell colloids into hydrophobic. Of a sixth theory (that of Warburg and his change of oxidation rate when protoplasm is narcotized) the author does not think much. He thinks even less of the most modern, seventh hypothesis of a "modification of the permeability of the limiting cell membrane." Pointing to the violent contradictions that appear at the very beginnings of experiment (some authors hold that permeability is increased, others that it is decreased) he asks sanely enough, "What is the mechanism of this permeability?" In similar fashion he pictures the inadequacies discovered and, therefore, the non sequiturs of any of the other hypotheses when looked at alone, emphasizing quite correctly however that there is nothing mutually exclusive in the several concepts of diffusion, adsorption, dehydration or flocculation of cellular content when viewed together. What he says in his criticism of the "permeability" theory covers in general his view of all the rest. "When we look the established facts well in the face we arrive at an impasse and these are all too numerous."

Taylor's Practice of Medicine By E. P. Poulton, M. A., D. M., F. R. C. P. With the assistance of C. P. Symonds, M. A., D. M., F. R. C. P. and others. Fifteenth edition. Cloth. Price \$8.50. Pp. 1136 with 175 illustrations. Baltimore: William Wood & Company, 1930.

The first edition of this book appeared in 1890. In the succeeding forty-six years there have been fifteen editions, the next to the last one of which came out in 1930. The new edition makes its appearance considerably revised and rather extensively changed, although the general arrangement of the previous editions is followed. To enumerate all the new features that have been incorporated would require unnecessary space, suffice it to say that the book has been brought to date. Incidentally the section on diseases of the tropics has been almost entirely rewritten. The first section deals with the infectious diseases and is preceded by an introductory chapter or section which explains in goodly part the mechanism of production of disease and disease signs in infectious diseases. The first subdivision has to do with diseases due to the ultrafiltrable viruses of unknown origin, then come Rickettsia diseases, represented solely by trench fever, the bacterial infections, the mycoses and the disorders due to spirochetes. The succeeding sections follow much the same order as most textbooks starting with diseases of the organs of respiration, followed by diseases of the nose, throat and ear. This portion has been largely rewritten. Next come diseases of the organs of circulation, the organs of digestion, metabolism and internal secretions and so on until the reader reaches an extensive section somewhat over 160 pages, on diseases of the skin. The last main division has to do with diseases of the tropics.

It is always difficult for an editor or the author of a textbook on medicine to know just where to place certain diseases. It seems odd to find almost all the rickettsial diseases listed under diseases of the tropics. Certainly Rocky Mountain spotted fever, as the name implies, would not by the broadest stretch of the imagination be called a tropical disease, nor does it seem logical to include amebic dysentery in the same category. Tularemia, a disease almost peculiar to the United States, is likewise considered a tropical disease, as is hydrophobia, another example of unusual classification. It is an old custom to include diseases of the skin in a book on internal medicine. It would seem much more sensible to use the nearly 200 pages devoted to dermatoses to a more complete and fuller discussion of pathologic physiology and treatment than is allowed in the present volume.

For the most part the material is well presented and lucidly written. There are many variants in an English textbook as contrasted with one written in the United States. The section on diseases of the heart makes an excellent example. In the first place there are a considerable number of arteriographic and polygraphic illustrations, methods of studying heart disorders which have been almost totally discarded in this country now that the electrocardiogram has been popularized. The terms compensation and failure of compensation are employed repeatedly. The lesions of the heart which are essentially of pathologic interest are rather full but the etiologic diagnoses are not incorporated in the text. No note is made, for example, of syphilitic heart disease or arteriosclerotic heart disease as such. On the other hand, rheumatic fever in toto is placed

in this section despite the fact that the lesions of rheumatic fever are essentially the result of infection and that other systems besides the cardiovascular may be involved in this disease. An extremely important condition, coronary occlusion is dismissed in one paragraph. Another peculiarity is that the various valve lesions are discussed individually and not in relationship to definite etiologic entities. The references to diseases of the organs of circulation, some seventy-three in number, are almost entirely English. There are four references to articles appearing in American journals, two of which are incompletely given.

The section on diseases of the blood, spleen and lymphatic system is reasonably complete, but it would certainly seem desirable to explain the mechanism of production of pernicious anemia. The reader is compelled to draw on his imagination when he comes across the term "extrinsic" factor, the quotation marks appearing as such in the text. There is certainly no note in the preceding portion of the section to explain what is meant by factors, either extrinsic or intrinsic. The macrocytic anemias, called megalocytic, are briefly described but no mention is made of that which occurs sometimes in advanced liver disease. It is doubtful whether pentnucleotide should be recommended for granulocytopenia.

From the comparatively few examples of what would seem to be sharp criticism, the implication might be that the book is not all that it should be. It would seem that the differences in terminology, variations in the consideration of disease and variances in therapy between English and American standards and customs would make the book a little difficult for use by the average American practitioner or student.

Der tuberkulöse Primärkomplex im Röntgenbilde Eine kritische Studie von J. P. Slooff, Kinderarzt am R. K. Krankenhaus O. L. Vrouw Meeder van Barmhartigheid, Eindhoven, Nr. 63. Tuberkulose Bibliothek, Behefte zur Zeitschrift für Tuberkulose. Herausgegeben von Dr. Franz Redeker, Oberregierungs- u. Obermedizinalrat Berlin und Dr. Karl Diehl, Dirigierender Arzt Sommerfeld. Paper. Price 8 marks. Pp. 80 with 61 illustrations. Leipzig: Johann Ambrosius Barth, 1937.

This excellent monograph on the tuberculous primary complex in the roentgenogram points out, in the introduction, that the combat against tuberculosis in children begins with the prevention of infection and therefore must consider following the infected individuals. The greatest significance pertains to the early stage of the disease when the process is limited to the primary complex, which in most cases is situated in the lung. To determine these cases, a periodically repeated tuberculin test and x-ray study are valuable. Physical examination of the lungs in these forms of tuberculosis possess little or no value. Roentgenology is viewed as the pathologic anatomy of the living. The studies reported are concerned with variations of the primary tuberculosis of the lungs (primary complex) in the x-ray examinations. The literature is reviewed from the point of view of (a) the anatomic literature and (b) the roentgenologic literature. In the anatomic review the Küss (18-5) Parrot (1876) gland-lung combination is cited with Georges Küss, in 1899, almost presenting the advances of modern initial tuberculosis, which was verified by E. and H. Albrecht, with Ghon giving the distributional data and Tendeloo accentuating collateral inflammation. While Tendeloo, Puhl and Koch indicate the primary foci to be where movement energy is greatest, Engel localizes them where the bronchi are shortest. Satas does not view primary complex as the first infection but as the first pulmonary change occurring. Engel clarified the glandular topography of the chest. The roentgenologic phases centered on the chest shadows and "free lung fields" which are veiled by the shadows of the ribs and soft parts. The marginal distinctness is influenced by the distance from the photographic plate. The air content of the pulmonary tissues also may cause deviations. Gräff and Küpfert using the Aschoff and Nicol scheme, stated that the density of the shadow increases with the density of the focus, but they were not particularly concerned with the primary complex. Ballin and Bigler found that small and even larger foci in vascular shadows might not be disclosed, while others found primary foci masked by shadows of the heart and liver, rib hilus and interlobular pleuritis. Bigler found that encapsulated and even calcified primary foci cast a definite shadow over 1 to 15 cm. No wonder Engel viewed the clinical appearance of the primary

complex to be that of bronchial gland tuberculosis. Redeker introduced the term "primary infiltration" to include the primary focus and collateral inflammation. Engels' correlation with the postmortem appearance was valuable. The author follows Engel's nomenclature. The 'butterfly' hilitis shadow is considered important in tuberculosis as is the blurring of the heart shadow. The author's technic and interpretation was based on twenty postmortem studies in cases of tuberculous meningitis: three of 1 year or younger, three of about 2 years, three of 3 years, one of 4 years, two of 5 years, two of 6 years, one of 7 years, three of 10 years, one a girl of 17 years, and a woman of 22. The roentgenogram before death was compared with the lungs after death. The technic used is detailed. The studies revealed twenty-five primary complexes of various extents. Twenty of these were found in the right and five in the left lung. In two cases two primary foci were found in one case three and in another case two groups of three or four foci which must be considered primary. The macroscopic appearance post mortem was compared with the x-ray appearance just prior to death. The dorsoventral x-ray examination with present day technic gives scant information on the extent of the variations present. This monograph should prove valuable to physicians and roentgenologists interested in childhood tuberculosis and the primary complex as well as to those interested in the problem of tuberculosis as a whole. It is well written and suitably illustrated.

Anestesia de base pela dialilmalonilurea (Estudo clínico e experimental) Pelo Ovidio Unti, assistente da Faculdade de farmacia e odontologia da Universidade de São Paulo. Tese Inaugural apresentada á Faculdade de medicina do Paraná. Paper Pp 172 with illustrations. São Paulo [n. d.]

This work, in Portuguese, deals with almalonylurea, a compound (diallylbarbituric acid, curral, diallylmalonylurea or dial) which is already used in general surgery. After experiments with animals, by using dial the drug was tried as a preanesthetic hypnotic, basal anesthetic and general anesthetic. Its action was compared with several other general anesthetics, especially barbituric compounds which have similar pharmacologic characteristics. Dial is classified among the narcotics of medium strength; it has an anesthetic effect of longer duration than sodium evipal or eunarcon and of shorter duration than somnifen and pernocton. Dial may be administered intravenously by slowly injecting a solution of the drug into a vein in the arm, and it also may be administered intramuscularly or orally. The dosage varies according to the individual and whether or not the effect desired is a basal anesthesia or a preanesthetic hypnosis. As a basal anesthetic the dose is 1 cc (0.1 Gm) of a 10 per cent solution for each 10 Kg of body weight. The patient may fall into a profound sleep at the end of the injection but as a rule, it takes from two to thirty minutes to induce sleep. Therefore it is recommended that thirty minutes should elapse and then, if necessary, minimal amounts of an inhalation anesthetic should be added. The inhalation anesthetic may also be used during operation when the need arises. When intravenous injection is not possible dial may be administered intramuscularly from forty to sixty minutes prior to operation. The anesthetic action is not as effective when the drug is administered by this route. The length of hypnosis is from a half to one and a half hours. As a preanesthetic hypnotic the dose is from one to one and one-half tablets or from 35 to 45 drops the evening before operation, and one hour before operation 0.5 cc (0.5 Gm) of a 10 per cent solution of dial for each 10 Kg of body weight is given in tablet form, in drops or by injection.

The author divides his work into three parts. The first part concerns general rules for anesthesia, especially for administration of the barbiturates (evipal, eunarcon, soneryl, numal, amtal, somnifen, pernocton and others). There also is a short description of the synthesis of dial. The second part deals entirely with the author's experimental work with laboratory animals (rats, dogs and guinea pigs) by using hypnotic or toxic doses of dial. The action of the hypnotic on the acid-base balance, leukocytes, erythrocytes, smooth and skeletal muscles, circulation and respiration was verified. The liver and kidneys of the animals were submitted to anatomicopathologic examinations. From these studies the author draws the following conclusions. When dial is administered in narcotic doses it has

no harmful effect on the organism of the animals studied, but toxic doses administered to animals produce a rapid and profound narcosis, accompanied by tonic and clonic convulsions, mydriasis and rapid death. Histopathologic studies of the liver and kidneys of the animals that received toxic doses showed degenerative changes. The narcotic dose has practically no harmful effect on the liver and kidneys, and these doses do not interfere with the respiratory rhythm. They produce general relaxation of all muscles. Toxic doses cause a diminution of the respiratory rate and sometimes produce respiratory arrest. In the third part of the study, the author describes the action of the anesthetic on the human being and gives the results of the necessary biochemical investigations. He reports the results in forty-five cases in which dial was used either as a preanesthetic hypnotic, basal anesthetic or general anesthetic, and draws the following conclusions.

Dial is efficient as a basal anesthetic and sometimes as a general anesthetic and, therefore, may be placed among the preanesthetic hypnotics and basal anesthetics. Dial induces anesthesia which lasts for an optimal length of time and which is sufficient for any surgical operation. The duration of anesthesia varies from twenty minutes to one and a half hours at the most. The patient loses and gains consciousness without any disagreeable sensation, and in the postoperative period the patient rarely vomits. Agitation and restlessness, which occur so commonly when anesthesia is induced by other barbiturates, rarely occur when dial is used. If the technic of administration of the anesthetic and the dose of 1 cc (0.1 Gm) of a 10 per cent solution for each 10 Kg of body weight is followed strictly, agitation and vomiting are avoided. Dial is an excellent addition to general or spinal anesthesia, when administered in a small dose, either orally or intramuscularly. It is an anesthetic that is easily administered, except by rectum. Although the anesthetic produces perceptible muscular relaxation, the use of an inhalation anesthetic is recommended for a short time as an additional anesthetic to obtain complete muscular relaxation. The author observed no toxic effects, even in debilitated subjects. Variations in blood pressure were usually very slight; there was a moderate rise in the systolic and diastolic pressures, therefore the drug attenuates the fall in blood pressure caused by operative maneuvers on the abdominal organs. There is no noticeable alteration of the pulse or respiration. Dial does not interfere with the acid-base balance, the blood sugar, the blood urea or the hemoglobin. The only cases in which dial is not recommended are those in which there is disease of the liver or kidneys. The author says that by continuing his studies he can prove that dial produces a more suitable anesthesia than that produced by inhalation anesthetics.

The results presented are interesting to those who are concerned with the use of the barbiturates.

Medical Urology By Irvin S. Koll, B.S., M.D., F.A.C.S., Attending Urologist, Michael Reese Hospital, Chicago. Cloth. Price \$5. Pp. 431 with 98 illustrations. St. Louis: C. V. Mosby Company, 1937.

The author's purpose, as stated in the preface, is to present the subject in such a manner as to be of practical value to the general physician and an aid to the medical student. The subject is divided into five parts. The first is devoted to diseases of the urethra and genitalia, the second to venereal ulcerative lesions of the external genitalia and adnexa, the third to diseases of the kidneys and ureters, the fourth to diseases of the urinary bladder, and the fifth to sexual impotence and sterility. The usual conception of urology as a surgical specialty is disregarded and, in keeping with the title of the book, the discussion is devoted to diagnosis and treatment, the technic of operations being omitted. The chapters on gonorrhea and complications in both male and female are excellent. Deserving of special mention is the chapter on venereal ulcerative lesions, which includes chancroid, erosive and gangrenous balanitis, granuloma inguinale and venereal lymphogranuloma. It is not a full text as evidenced by the omission of tumors of the testes, kidneys and bladder. Malformation and anomalies receive scanty mention. The portion devoted to diseases of the kidneys and ureters and the bladder would for the most part be considered orthodox urology. In the chapter dealing with instrumental treatment of infections of the kidney, the statement that any medical man in one month can be trained sufficiently in the

technic of ureteral catheterization to treat this type of case satisfactorily" is deplored on the ground that unless an expert is available the treatment had better be dispensed with altogether. A chapter on nervous diseases deals with the functional and symptomatic and the organic diseases affecting urination. Syphilis of the bladder is given a short chapter, which will be of interest to the general physician as well as to the urologist. A final chapter on differential diagnosis will be of especial interest to students. On the whole the book is well illustrated, readable, concise and practical.

Surgical Treatment. A Practical Treatise on the Therapy of Surgical Diseases. By James Peter Warbasse M.D. F.A.C.S. Special Lecturer in the Long Island Medical College and Calvin Mason Smyth Jr. B.S. M.D. F.A.C.S. Assistant Professor of Surgery in the University of Pennsylvania. In three volumes with separate index. Second edition. Cloth. Price \$35 per set. Pp 906 782 798 131 with 2 486 illustrations. Philadelphia & London W. B. Saunders Company, 1937.

Because the author makes no attempt to discuss diagnosis or pathology, he succeeds in covering a much larger field than would seem possible. The aim is mainly toward the active practitioner. An effort is made to discuss the therapeutic questions that may confront the average surgeon. It cannot therefore be classified as a textbook. There is no bibliography and the style is in the personal narrative form. The author states that for each disease he describes at least one technic which any average surgeon is qualified to try. Surgical competence, however, is still a matter of individual variation and many of the operations described are not within the technical scope of most men. The longest sections are devoted to the more common surgical problems. For example, Colles's fracture of the wrist is given comparatively thorough attention as far as treatment is concerned, while others, such as fractures of the carpal bones, are no doubt underemphasized. The treatment of appendicitis is set forth satisfactorily and, while only the classic McBurney incision is described in detail, other modes of therapy are suggested and the complications are well handled. The author's suggestion of right rectus incision for the less experienced is good and is indicative of the tone in which the writing is done.

The scope of this work is ambitious. It begins with general surgical principles and ends with a chapter on medical economics. The last, although not scientific, is interesting. The author's position on cooperative medicine is well known.

There are chapters on physical therapy, surgery of ailments and injuries of the new-born, gas poisoning and first aid. The section on anesthesia is fairly complete and there are numerous hints and suggestions as to methods of choosing local and general anesthetics. Surgery of the head and brain, gynecologic surgery and genito-urinary and pelvic surgery are included. Surgical treatment of diseases of the eye, ear, nose and throat is discussed under the section on the head and, while naturally incomplete because of obvious limitations, includes most of the conditions the general surgeon is called on to treat. Tonsillectomy is described in detail and in a practical manner, the method of enucleation being given first choice. There are descriptions of standard abdominal operations with the usual slight personal modifications in technics. A helpful adjunct is the inclusion of dietary regimens and schedules, so that the whole therapy of a peptic ulcer is given together. Preoperative and postoperative care is also well handled, including the administration of fluids and the use of nasal suction and other more recent devices. An interesting point is raised with the suggestion that the internist devote more time to postoperative care and that he be consulted earlier postoperatively and have joint charge of the patient. Wherever possible the author gives much medical and therapeutic advice which is not directly operative but which is part of the treatment in general.

The illustrations are numerous, skilfully drawn and clear. Some of the photographs are of doubtful value and may be unnecessary. The arrangement of the subject matter is a bit difficult because of the absence of pathologic and diagnostic features, which are as necessary to classification as is anatomy, and this occasionally spoils the continuity. But this is no real drawback and serves at times to economize space. On the whole, this surgical treatise may be recommended to every general practitioner and to the average surgeon as a practical addition to the library.

Les hyperglycémies. Étude clinique et physiopathologique. Par H. J. Warembourg médecin des hôpitaux de Lille. Préface de MM. les Professeurs Loeper et Polonovski. Papier. Price 65 francs. Pp 551 with 21 illustrations. Paris. Masson & Cie 1936.

This comprehensive monograph, combining a keen and critical review of the hyperglycemias with experimental work, deserves universal recognition. The author blends his scientific experience in the laboratory of biologic chemistry and the wards of the medical clinic in the charity hospital in Lille with a wide knowledge of the literature of hyperglycemia, of which the volume includes approximately 1,800 references. The latter is particularly valuable for American readers because, although the American literature is freely quoted, many articles that might escape attention in the foreign literature are mentioned. The volume consists of a preface by the heads of the department of biologic chemistry and of clinical medicine. The first portion of the book analyzes the subject of hyperglycemia from a general point of view and the results of the author's researches on the constitution and significance of the total undetermined carbon of the blood plasma. In the second part the hyperglycemias as produced physiologically and experimentally are discussed, with application to the glycoregulatory functions as seen in the clinic. In the third portion is a study of diabetic hyperglycemia, diagnostically, prognostically and from the point of view of treatment. The aid which the determination of the residual carbon of the plasma brings to a solution of these problems is developed in detail. In the fourth part the pathologic hyperglycemia of nondiabetic origin is considered. This includes hyperglycemia in the diseases of the liver, heart, lungs, endocrine glands, digestive system and nervous system. Further more references are made to disturbances of carbohydrate metabolism in infections of the skin, cancer, postoperative disease and obesity. The whole volume attempts to clarify this complex problem of hyperglycemia and to portray it in relation to facts and bring practical conclusions for clinical work on the amount of glycemia and an appreciation of the measure of the intermediary derivatives of glucidic metabolism in the plasma as determined by the index, *chromique résiduel*.

Report of the Seventh Australian Cancer Conference Held at Melbourne 4th-8th May 1936. Commonwealth of Australia. Papier. Pp 19 with 9 illustrations. Canberra. L. F. Johnston 1936.

This report contains a general review of developments in cancer control in Australia during 1935 by Dr. M. J. Holmes, the review of the activities of the Commonwealth X-ray and Radium Laboratory and the physical services in the states for 1935 by Dr. C. E. Eddy, the review of developments of cancer control in New Zealand during 1935 and a review of Australian cancer mortality statistics by Dr. Holmes, as well as the paper read by Dr. Eddy on *Some Recent Developments in Radiological Physics*.

From the general clinical point of view the cancer statistics presented by Dr. Holmes are most interesting. The mortality statistics demonstrate definitely that the mortality curve from cancer shows a steady tendency upward although fluctuations do occur. This increase is in definite relation to the older age grouping of the population, as is also shown elsewhere. Most interesting, however, is the proportion which cancers of the different organs have in this increase of cancer mortality, which is not explained by the change of age distribution alone or by the improvement in diagnostic or therapeutic facilities. Cancer of the tongue shows a definite diminution of the mortality rate in men, whereas the death rate from cancer of the tongue was 39 per hundred thousand of mean population in 1908, 1934 showed a death rate of 29. The death rate from cancer of the female genital organs on the other hand shows an increase from 153 in 1908 to 212 in 1934. The increase for the decade 1913 to 1923 was 16 for the decade from 1923 to 1933 it was 46. In a similar manner, cancer of the female breast shows an increase from a death rate of 10.2 in 1908 to 20 in 1934. The rise in the mortality rate of cancer of the breast shows a 96 per cent increase in the past twenty-six years as compared with a 38 per cent increase in the mortality rate of cancer of the female genital organs.

Cancer of the rectum and anus shows a rise in the mortality rate. In men there is an increase of 170 per cent in the past

twenty-six years, in women of 39 per cent. In cancer of the digestive tract considered together (esophagus, stomach, intestine, rectum and anus) an increase of 120 per cent in men and of 87 per cent in women is noted between 1908 and 1934. In cancer of the skin the mortality rate in men rose steadily until 1918, from 3.1 in 1908 to 5 in 1918. Since then the rate has been lower (3.4 in 1928 and 4.2 in 1934).

These statistics show, therefore, in agreement with those by other authors, a definite difference in the change of incidence of the cancer mortality for cancers of different organs. These changes are not wholly explainable by an improvement in the conditions of diagnosis and treatment. Cancer of the female breast, for example, shows an increase in spite of the fact that certainly the chances for early surgery have improved. The mortality rate for cancer of the female genital organs has increased considerably in spite of improvement in the conditions of treatment today. On the other hand, in cancer of the tongue, for instance, a definite decrease is noted although the conditions for treatment have not been much improved.

Principles and Foibles of Cancer Research in Regard to Etiology and Nature. By William Rlenhoff, Sr. M.D. F.A.C.S. Paper. Price \$2.50. Pp. 200. Baltimore: Waverly Press, Inc. 1936.

The author discusses the different phases of cancer research from a rather philosophical watch tower. The details of the elaborate discussions are not suitable for review. The general scope is best indicated in the author's own words: "For the most part the proposed explanatory theories are mere paraphrases of existing obvious conditions. Others are theoretical speculations, visionary hypotheses or rather guesses, unsupported by concrete facts. Imagination has been given free scope; regard to facts has given way to arbitrary autochthonous ideas, of which there has apparently been no dearth."

Radiumdosimetrie. Verfahren und bisherige Ergebnisse. Von Dr. Karl G. Zimmer, Assistent an der Strahlenabteilung des Cecilienhauses Berlin Charlottenburg. Mit einem Vorwort von Priv. Doz. Dr. A. Pickhan, Direktor des Cecilienhauses. Fortschritte auf dem Gebiete der Röntgenstrahlen. Ergänzungsband XLIX. Paper. Price 6.50 marks. Pp. 40 with 33 illustrations. Leipzig: Georg Thieme, 1936.

This booklet gives a convenient survey of the methods of radium dosimetry. Its title expresses at the same time the fact that the field is still in a developmental state and that this publication presents only the present situation without claiming final disposition of the problem. Radium dosimetry is discussed from two points of view: first as what the author calls "relative dosimetry" dealing with the special distribution of radiation in the neighborhood of radium preparations and, second, "absolute" dosimetry. This is the investigation of the practicability of a unit of dosage and its realization. In the first part, on relative dosimetry, the ionometric method is discussed and the instruments described; the photographic biologic methods of radium dosimetry as well as the mathematical methods are also discussed. This chapter is concluded by a comparative investigation of these methods, in order to draw conclusions concerning the range of applicability of each. In the second part on absolute dosimetry the roentgen is accepted as the suitable unit for gamma ray dosage, and the problems related to these measurements are discussed. In an appended chapter on special problems of radium dosimetry the situation with regard to the radium bomb and the measurements for adequate protection are discussed.

Hypnotic Power: Its Cultivation, Use and Application to Psychotherapy. By Colin Bennett. Cloth. Price \$1.50. Pp. 158. New York: F. P. Dutton & Co., Inc. 1937.

This small book, from British sources, is apparently written by a layman for laymen. The author states frankly that the book aims no higher than to be a psychotherapeutic "home doctor." For those who wish to learn the art of hypnotism, much information, based on actual experience, is here recorded. The author's plea that the "ordinary person" be allowed to practice hypnotism is not in accord with the best standards of medicine. There are many qualified physicians, at least in the larger medical centers, who use hypnotism as a form of treatment. The need for lay hypnotists is not so urgent as the author would have us believe.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Workmen's Compensation Acts. Agranulocytosis in Relation to a Fall.—The workman, about 51 years old, during the course of his employment reached up to remove a tag from a small "blister" car standing on a narrow gauge railroad track 30 inches wide, which track rested on a dirt fill about 12 inches high. Without any apparent outward cause he slipped slowly to the ground, endeavoring to check his fall by holding on to the car, which was not in motion. He attempted to rise but was apparently unable to do so. So far as the evidence showed, the fall produced no contusion on his body. The workman was taken home, where he remained under treatment for about five months. On the occasions when he was out of bed he walked with great difficulty and with a spastic gait. His back gave him much pain, and his legs, as well as an area near the lower end of his spine, seemed numb. Prior to the time of the fall, he was usually able to walk without difficulty, although as early as 1926 he had symptoms of numbness and trembling of his feet and fingers, and on occasions pain over the distribution of the left sciatic nerve. He died October 6 from agranulocytosis, according to the physician who attended him. His widow instituted proceedings under the workmen's compensation act of Texas and, from a refusal of the industrial accident board to grant compensation, appealed to a state court. Because of diversity of citizenship, the action was removed to the federal district court, which directed a verdict for the defendant, and the plaintiff appealed to the United States circuit court of appeals, fifth circuit.

Previous to his fall in 1935, the workman had suffered from a long series of ailments. Prior to 1925 he had developed pulmonary tuberculosis for which he underwent treatment in a sanatorium. As early as 1925 he suffered from backaches and had a chronic sinusitis and quinsy. In 1926 he complained of vertigo and constant backache, and suffered with severe digestive disturbances, dysentery or other intestinal trouble. On two occasions in 1926 and in 1927, when under the stress of excitement or anger, he fainted. Excitement and anger seemed to cause a return of diarrhea, with which he was frequently affected. In December 1933 he was again suffering from diarrhea, fever, vomiting and dizziness, and Aug. 13, 1934, he sustained an injury to his back, which developed into a typical lumbago, which incapacitated him for eleven weeks. During these various illnesses, beginning as early as 1925, the workman took a "prepared medicine, a coal tar product, the use of which if continued for a long length of time results in granulocytosis [agranulocytosis], a disease of the blood which destroys the white blood cells leaving the body without adequate defense against infection." The testimony of the physician who attended the workman at the time of his death, and that of another physician who had treated the workman intermittently for ten years, was to the effect that there was no causal connection between the fall and the death.

The widow contended that her husband died from a compression myelitis of the spinal cord resulting from the physical violence of his fall and in support of this contention called attention to the workman's spastic gait and paralysis and numbness of the lower extremities as being symptoms of a compression myelitis. The undisputed testimony was that some form of external violence sufficient to injure the bone is necessary to produce a compression myelitis. There was no testimony, the court said, medical or lay, that the workman suffered from myelitis or that his fall was of sufficient violence to cause a compression myelitis. The widow's assertion that her husband died from that disease rested on no foundation other than the presence of symptoms which are common both to myelitis and to agranulocytosis. A verdict for her on the theory that the workman died of myelitis would, the court said, be directly opposed to the unequivocal and uncontradicted testimony of the physician who attended the workman at his death who said that death was due to agranulocytosis and of the testimony of

both that physician and the other physician who attended the workman for ten years, that the fall had no causal connection with his death. When this uncontradicted testimony is viewed in connection with the workman's extended medical history, the court concluded, and the uncontradicted evidence of his continued use of a "prepared medicine which will ultimately cause granulocytosis [agranulocytosis]," and there being no substantial evidence to support the widow's theory of death from myelitis or that the fall was of sufficient violence to produce a myelitis, only one reasonable inference can be fairly and reasonably drawn, and that is that the workman's death resulted from disease unconnected with the fall. A contrary conclusion would be wholly conjectural.

For the reasons stated, the judgment of the district court for the defendant was affirmed.—*McVerry v Fidelity & Casualty Co of New York*, 87 F (2d) 963

Insurance, Accident Abscess of Brain in Relation to Overexertion—The defendant insurance company promised to pay certain benefits if the insured died as a result of external, violent and accidental means. The insured, aged 40 years, was a strong, healthy, well nourished and robust person, accustomed to performing hard labor. On March 30, while attempting to lift a 95 pound sack of cement into a wheelbarrow, he suddenly lost the use of his legs and fell to the ground. He was lifted into an automobile and after receiving medical attention at the office of a physician he was taken home and put to bed. At that time he was in a semiconscious condition, was pale, and was still unable to use his legs. That afternoon he was removed to a hospital. An examination made of his heart, lungs, eyes, ears, bladder, liver and nose disclosed no defects in any of them. His temperature and pulse readings were normal. Fifteen days later, on April 15 his temperature began to rise and his pulse rate increased. From a normal reading of 20/20 on April 5, the vision of both eyes was reduced to 20/200 on April 18. He gradually grew worse, went into coma and died April 18. A postmortem examination disclosed an abscess of the brain, which admittedly was the cause of death. The insurance company refused to pay the benefits provided in the insurance policy, contending that there was no evidence that the death was caused through external, violent and accidental means. The plaintiff, as beneficiary, brought suit, and from a judgment against it in the trial court the company appealed to the appellate court of Illinois, fourth district.

An expert witness for the beneficiary testified that the abscess of the brain from which the insured died began about April 14 or 15, when the hospital records showed that the insured had a high temperature and his pulse rate was above normal and his vision was greatly reduced. At the time the insured lifted the sack of cement in the opinion of this witness, there was an alteration or impairment in the circulation of the blood supplied to the brain, caused either by a small hemorrhage or by the break or rupture of a blood vessel in the brain, and that this condition resulted in a thrombosis, which comprised the seat for an infection which later developed, causing the abscess in the brain. He testified that the lifting of the sack would or could have been sufficient to produce a hemorrhage or rupture of a blood vessel in the insured's brain and that from the evidence contained in the hospital records the deceased had no other condition or infirmity which could be the cause of death. The appellate court adopted a definition of "accidental means" laid down by the Supreme Court of the United States in *United States Mutual Accident Association v Barry*, 131 U S 100, 9 S Ct 755, as follows:

that if a result is such as follows from ordinary means voluntarily employed in a not unusual or unexpected way it cannot be called a result effected by accidental means but that if in the act which precedes the injury something unforeseen unexpected unusual, occurs which produces the injury then the injury has resulted through accidental means.

In view of the foregoing definition the appellate court thought that the jury committed no error in finding that the death of the insured resulted from external, violent and accidental means independent of all other causes. The evidence continued the court showed a complete chain of circumstances from the time the insured left his home on the morning of the accident until the hour of his death. There was no intervention of time unaccounted for, and the jury was warranted in view of the

facts proved and in the absence of any testimony as to any other cause of his death, to infer that the disability he sustained in attempting to lift the sack of cement was the proximate, sole and only cause of his death.

The judgment for the beneficiary was therefore affirmed.—*Paoli v Loyal Protective Ins Co (Ill)* 6 N E (2d) 960

Hospitals Liability for Tuberculosis Contracted by Baby from Nurse—The plaintiff's son was born at the defendant hospital, June 19, 1935, and during the next six days it was attended by nurses in the maternity ward. One of these nurses had a severe cold and a chronic cough which had been present for about six weeks. She was subject to severe coughing spells and some of the seizures took place while she was caring for the baby. The nurse did not use a mask, as was required by the rules of the hospital to be worn by nurses when attending babies, but did cover her mouth with her hand during a coughing spell. While her chronic cough and cold were well known to the other nurses and patients in the maternity ward, the nurse did not report her condition to the superintendent of the hospital. On or about June 25, an x-ray examination of her chest failed to reveal positive evidence of pulmonary tuberculosis but tubercle bacilli were found to be present in her sputum and she was placed in a sanatorium. On June 30 the baby was taken home from the hospital. Within two weeks thereafter it became ill and was returned to the hospital. It died, August 22, from acute miliary tuberculosis. The plaintiff, as special administrator of his son's estate, sued the hospital alleging that his son's death had been caused by its negligence. The jury returned a verdict for the plaintiff and when the trial court denied the hospital's motion for a judgment notwithstanding the verdict, the hospital appealed to the Supreme Court of Minnesota.

There was sufficient evidence in the opinion of the Supreme Court to sustain the jury's finding that the disease from which the baby died was contracted from the nurse. While the superintendent of the hospital testified that she would have relieved the nurse from duty had she reported her condition, as the rules of the hospital required, yet it appeared that the superintendent visited the maternity ward at least once each day and the court could not conceive how the superintendent could have been ignorant of the nurse's condition when it was known to the other nurses and to the patients. It was the superintendent's duty to exercise due care to see that her nurses were free from communicable disease, and the jury was justified in finding that she should have ascertained what was generally known and should have taken the nurse off duty. Even if the nurse had only a common cold, ordinary prudence would have prevented the hospital from permitting her to attend the babies, as the infectious propensities and the often serious consequences of the common cold are well known. The court further held that it was not error for the trial court to permit the hospital chart to be introduced in evidence, citing *Lund v Olson*, 182 Minn 204, 234 N W 310, 75 A L R 371.

The Supreme Court therefore, affirmed the order of the trial court denying the hospital's motion for judgment notwithstanding the verdict for the plaintiff.—*Taafe v St Olaf Hospital (Minn)*, 271 N W 109

Workmen's Compensation Acts Softening of Brain in Relation to Herniotomy—In February 1929 Jenneman sustained a hernia in the course of his employment with the defendant company. A herniotomy was performed but the hernia recurred in May 1930. On Dec 1, 1930 a second herniotomy was performed by one of the company's physicians. During his stay in the hospital for his second herniotomy, the employee contracted a cold and pleurisy on his right side and phlebitis in his left leg developed. He also had headaches, elevated temperature, and on two occasions while walking about the room in the hospital his right side became numb, his right leg weakened, and he fell. He left the hospital Jan 24 1931. He returned to work April 15 1931, and continued to work for fifteen days. During this time he lost interest in his personal appearance and family, constantly suffered pain on the left side of his head, could not use his right hand and in walking dragged his right foot. Later he was able to speak only with difficulty and was unable to write. His condition became worse and he died May 14 1932. His dependents

claimants, instituted proceedings under the workmen's compensation act. The commission denied compensation but the lower court reversed the commission's order and remanded the case. The defendants thereupon appealed to the Supreme Court of Missouri, Division No 1.

The medical testimony was in accord that the cause of the workman's death was softening of the brain, that the softening of the brain was caused by a thrombosis in a branch of the middle cerebral artery, that the thrombosis was caused by arteriosclerosis, and that the hernia did not directly cause death. The physicians called by the claimants testified that the last herniotomy caused the cold, pleurisy and phlebitis, that the pleurisy or phlebitis or both either caused or aggravated the arteriosclerosis, and that the arteriosclerosis in turn caused the thrombosis. On the other hand, the physicians called by the defendants testified that neither the hernia, cold, pleurisy nor phlebitis in any manner caused or aggravated the arteriosclerosis. They were of the opinion that the pain, dizziness and suffering experienced by the deceased after the last operation were due to "cerebral angiospasm."

The claimants challenged the testimony of a physician because he had submitted two reports of the autopsy, the first one failing to record the presence of arteriosclerosis in the region of the [middle] cerebral artery. But, said the Supreme Court, this physician testified that after submitting his first report he had continued the examination with the aid of a microscope which disclosed the arteriosclerosis. He further testified that he had submitted specimens to other physicians who made microscopic examinations, and all agreed that arteriosclerosis was present in the region in question. His submission of two reports on the autopsy was properly for the consideration of the commission in weighing his testimony.

In the opinion of the Supreme Court, the ruling of the commission denying compensation was supported by substantial evidence. Accordingly, the judgment of the lower court was reversed and the case remanded with directions to affirm the order of the commission—*Jenneman et al v Consolidated Underwriters Same v Scullin Steel Co (Mo)*, 100 S W (2d) 458.

War Risk Insurance Incipient Pulmonary Tuberculosis in Relation to Total and Permanent Disability—A finding of total and permanent disability sufficient to mature a war risk insurance contract cannot be sustained, said the United States circuit court of appeals, eighth circuit, on proof showing merely that tuberculosis was present in an incipient stage. The disease in its early stages is not an incurable malady and in a large proportion of cases it may become arrested so that the patient may engage continuously in some substantially gainful occupation—*United States v Cameron*, 87 F (2d) 61.

Gold Salt Therapy in Chronic Arthritis

DRS R GARFIELD SNYDER, FRANZ J LUST, CORNELIUS H TRAEGER and LEMOINE C KELLY, New York. Various preparations of gold have been used in arthritis, such as allochrysin, solganol, myoral, sanochrysin, myochrysin, lipaural, chrysalbum, lopion, aurocein and gold sodium thiosulfate. These salts contain varying concentrations of metallic gold, usually between 30 and 50 per cent. There are organic and inorganic preparations, and many may be administered intravenously or intramuscularly. There is a wide range in the dose that may be employed. It is obvious from the high percentage of toxic reactions obtained in the past that the doses commonly employed were too large. There is no doubt that all gold salts are toxic, some more so than others, but susceptibility to this medication varies with the individual. Some European observers are of the opinion that doses large enough to produce reactions must be employed in order to get the best clinical results. Forestier advises starting with small doses of 10 mg, gradually increasing according to the tolerance of the patient, if the patient seems to be benefiting by this type of therapy. Some workers who use gold salts intramuscularly started with doses of from 200 to 500 mg. However, most men use small doses when giving gold intravenously.

The exact explanation of the beneficial results of gold therapy is not known. We do know that gold is excreted to a large extent by the kidneys during the first twenty-four hours. The rest is deposited in the mesenchymal tissues and stimulates the reticulo-endothelial system or, in other words, stimulates leucocytosis. In order to avoid cumulative effects, most writers advise that injections be given once a week for eight or ten weeks, in the same way that arsphenamine is given, followed by a rest period of from one to two months. It is at present generally agreed that not more than 1 to 2 Gm should be given during each series in order to avoid cumulative toxic results.

In the Arthritis Clinic of the Hospital for Ruptured and Crippled we undertook a survey of 100 cases. In order to determine the true value of this therapy, we selected cases that had proved resistant to all other forms of orthodox treatment. Any degree of improvement in this group would indicate that gold therapy had a definite beneficial effect. In an effort to guard against toxic reactions we eliminated any persons with a history of skin, liver, kidney or intestinal irritability. In addition to this precaution we eliminated all patients who gave a history of blood dyscrasia, which is the most serious complication. Each patient had a complete blood count, urinalysis and sedimentation rate before starting treatment and at frequent intervals during the course of treatment. At the first evidence of skin irritation, treatments were stopped. Usually the first symptom is itching. A slight trace of albumin in the urine is not necessarily serious but should make one cautious, especially with regard to increasing subsequent dosage. In most of these cases we used gold sodium thiosulfate, administered intravenously in doses starting with from 5 to 10 mg, with gradual increase up to the point of tolerance, our largest single dose being 125 mg.

In our series we did not observe any spectacular results, but there seemed to be various degrees of improvement in about 45 per cent of the cases. We also observed some improvement in about 35 per cent of the patients with osteoarthritis, contrary to Forestier's experience. There were seventeen toxic reactions. In eleven of these the results were mild dermatologic eruptions, which persisted for from three days to a week. In one case the rash lasted two and a half months. Another patient was delirious for two days and had dyspnea as a result of edema of the glottis. This was finally relieved by tracheotomy. Both patients had only two injections of gold sodium thiosulfate given intravenously, the first of 10 mg and the second of 20 mg. Both completely recovered from arthritis after these severe toxic reactions subsided.

The conclusions reached were that 1 Gold sodium thio-sulfate can apparently be given intravenously in doses ranging from 10 to 125 mg without serious danger in the great majority of cases, provided reasonable precautions are observed in the selection. To avoid toxic reactions the first two or three doses should never be above 10 mg. Since gold salts are toxic and the best results are usually obtained by large doses, it is obviously not at present a safe drug to put in the hands of the general practitioner. 2 Our results show various degrees of improvement in 45 per cent of the cases, but these particular cases had previously proved refractory to every other orthodox form of treatment. 3 Gold therapy deserves further careful consideration and study in the well organized clinics of this country in an effort to arrive at a true evaluation of its worth in various types of arthritis, especially those that have shown no response to other well known forms of treatment. An effort should also be made to find out which salt is the most efficient and the least toxic.

DISCUSSION

DR H ARCHIBALD NISSEN, Boston. The *Cumulative Index Medicus* from 1932 through 1936 lists 3,229 articles on arthritis of which 976 dealt solely with treatment. On an average, 638 articles a year have been published for the past five years, and 195 (or 30 per cent) each year dealt with treatment. Of the 976 papers published in five years on treatment, 245 discussed general treatment, not any specific form of therapy. Of these papers on special types of treatment, eighty were on gold therapy. Apparently the first publication on gold therapy appeared in this country in 1936, and to date I find that only four others on this subject have been published in this country. Dr Snyder has organized and is carrying on a wonderful follow up of his group of patients, especially this group receiving gold treatment. I asked Dr Lust, who gives the injections, what he considered the outstanding results of the gold treatment, and he said primarily the reduction of pain, definite decrease in swelling, and an increase in the functional activity of the joint or joints involved. That was some months ago, he may have found out differently since then. He believed that the gold salt preparation assisted in the absorption of scar tissue formation. I am particularly anxious to hear what his yearly follow up on this same group of patients will show. At the end of a five year period, its actual value should be evident.

DR M HENRY DAWSON, New York. We are under a debt of obligation to Dr Snyder and his associates for their judicial appraisal of this controversial subject. I should like to endorse Dr Snyder's statement that gold salts are not a form of therapy to be used by the general practitioner. They should not be used by any one who has not had extensive experience. Their use is not unattended with danger. The second point concerns the therapeutic results. What we do not know sufficiently in rheumatoid arthritis is the natural course of the disease. The only follow-up series with which I am familiar is one of 140 cases reported by Schneyer. At the end of fourteen years 56 per cent of the patients were still able to earn their own living and 22 per cent were unimproved. That is the general experience—about one fourth do well, about 50 per cent improve with good medical care, and about one fourth do badly. To state that 60 or 70 per cent improve on this or that therapy has little significance. Dr Snyder's results in osteo-arthritis were apparently the same as in rheumatoid arthritis. That is contrary to the reports of Forestier. He states that gold therapy is not indicated in osteo arthritis. Copeland states that gold salts can even be actually harmful in osteo-arthritis. In Europe and on the continent the use of gold salts is confined to rheumatoid arthritis. It is difficult to explain the enthusiasm of the European workers. It may be as Dr Snyder says that we are not giving the right dose. It will be interesting to hear a follow-up report after a number of years.

DR K K SHERWOOD, Kirkland Wash. I have had a rather extensive experience with the use of gold salts in the last two years. I wish to emphasize one point with regard to toxicity. I have found that itching occurs prior to other serious complications. If the therapy is stopped at that time no serious trouble results. I think the difference between Dr Snyder's results in hypertrophic arthritis and the results of the European observers may lie in the type of case. I have found in

hypertrophic arthritis with neurologic symptoms a fair response to gold in control of pain. In the other types of arthritis the result was nil. In rheumatoid arthritis it does help to control the symptoms. Its use in the first two or three months of treatment is of value in giving the patient confidence and in gaining an initial response which enables one to continue further treatment.

DR JACQUES KRONER, New York. One must be careful in estimating results. May I say as one who used this gold therapy for the last five years that I feel that injections of gold salts are a valuable form of therapy in rheumatoid arthritis. Many of the speakers emphasized the good results secured in Europe. I deem it important to avoid toxic effects in the skin. I have witnessed three cases of fatal toxicosis following the use of gold therapy. Since there is now an American product, gold sodium thiosulfate, this remedy in skilful doses and only for rheumatoid arthritis gives good results. I know of only one other remedy which is able to improve the sedimentation rate as well as gold does, namely, bee venom. I believe that when one has a case of rheumatoid arthritis which is intractable to other forms of treatment one should use gold salts in the form of gradually increasing doses and so avoid toxicity. A condition *sine qua non* is a fairly good general condition, a perfectly intact renal function, and its regular examination during the administration of gold salts.

DR R GARFIELD SNYDER, New York. In evaluating the European results on gold therapy it must be remembered that spa treatment or other forms of physical therapy were used in conjunction with gold therapy. In our two years experience with gold therapy the sedimentation rate was not a reliable guide as to prognosis. In some cases sedimentation went down as the patient improved, but in others it remained at a more or less constant level. In some cases, however, it was actually increased. These results might be different over a five year period. Contrary to Forestier's report, we found that some benefit was derived from the use of gold salts in cases of osteo-arthritis. This would seem to indicate that in addition to degenerative changes there may be also a low grade infection present as a factor in the etiology of osteo arthritis.

Fatal Rheumatic Fever

DRS EDWARD F BLAND and T DUCKETT JONES, Boston. Since 1921 (sixteen years) approximately 1,500 children and adolescents under the age of 21 years have received hospital care at the House of the Good Samaritan for rheumatic fever and chorea. The subsequent course and present status of this large group are known. We have presented in this report data relevant to the 306 patients who have died. A postmortem examination was performed in seventy-four instances (24 per cent). Rheumatic fever has been the outstanding cause of death and was directly responsible for the fatal issue in 250 instances (82 per cent). The course of events in this fatal group emphasizes the importance of the early years after the onset of the disease. Furthermore, from the data presented it is evident that they constitute a critical period which determines in large measure the future course of the disease. The manifestations of severe rheumatic fever differ profoundly from the generally accepted clinical picture of the disease and are often confused with primary disease of the lungs (pneumonia), the kidneys (acute nephritis) or uncomplicated heart disease.

The Transportation of Rheumatic Fever Patients to a Subtropical Climate

DRS T DUCKETT JONES and PAUL D WHITE, Boston and C F ROCHE, JEAN JONES PERDUE and H A RYAN, Miami Beach, Fla. Since 1930, twenty six patients with rheumatic fever and rheumatic heart disease have been transported from the House of the Good Samaritan, Boston, to the St Francis Hospital, Miami Beach, Fla. The patients have been sent South in groups of four and six each year (save for the winter of 1935-1936) and have remained south during the winter season (from six to eight months). Five children have had two winter seasons each in southern Florida. The hospital care in the North and the South has been comparable. There was a decided annual variation in the improvement from transportation. Three patients died in Florida, two of continuous severe rheumatic fever and one of recurrent rheumatic fever after seven months in Florida. In eleven the rheumatic fever became

quiescent, in nine the rheumatic fever showed definite improvement, five were unimproved and two were worse. Four children are at present in Florida, in one instance it is the second winter season there. Recurrences of rheumatic fever occurred in Florida following sore throats, colds, unexplained fever and without apparent precipitating events. Since returning to Boston eight have remained well while twelve have had recurrences of rheumatic fever. Three patients died within a year after returning to Boston, and one in the second year. Forty further patients with rheumatic fever and rheumatic heart disease have been observed in southern Florida. The duration of their stay has been variable. Twenty-five had active rheumatic fever at the time they went south in Florida (after variable periods), sixteen of these became quiescent, six were unimproved, one was worse and two died. Recurrences were noted as in the House of the Good Samaritan group, and four of the recurrences followed severe sunburn (one fatal). Rheumatic fever and rheumatic heart disease subjects, living in such a climate, seemed to be protected to some extent but not invariably. In both of these series the patients with mild rheumatic heart disease or early mild rheumatic fever seemed to improve more strikingly, as would be expected. Caution is expressed with regard to the unquestionable value of transportation to a subtropical climate. Respiratory infections are frequently observed in southern Florida. Despite their frequency, hemolytic streptococcus infections are less common and less severe than in Boston, as shown by throat cultures and the development of hemolytic streptococcus immune bodies.

DISCUSSION

DR WILLIAM D STROUD, Philadelphia. The study reported by Drs Jones and Bland bears out the results of our study at the Children's Heart Hospital in Philadelphia. Although in the last fifteen years we have had only about 700 cases, as compared to their 1,500, and have not been able to follow those cases as carefully as they have, we have a death rate of 50 per cent, which is 7 per cent higher than their 43 per cent. There are several points in the first presentation, of Drs Jones and Bland, which help us clinically. First of all, of the children who died the vast majority died as a result of an upper respiratory infection reactivating rheumatic fever and not as a result of physical effort. We are therefore able to reassure the parents of these children that, in the average case, normal physical effort will not damage the heart so long as there is no evidence of rheumatic activity. The fact they had only seven sudden deaths bears out this point. The patient who lives in danger of sudden death from coronary disease is certainly in a different situation than the child with rheumatic heart damage and one must make sure both the patients and the parents realize this fact. In the second paper, Dr Jones and his associates have suggested that Florida and southern California are the best places for these patients during the winter months. I think that even those who live in those states must admit that they have damp, windy, cold days. If such days occur after an upper respiratory infection, the environment for from twenty-four to seventy-two hours is not much different from a little farther north. In Philadelphia we have used intravenous therapy and every week during the winter months have given the children whole blood of adults of nonrheumatic families. This has proved ineffective. At present we are interested with Dr Stokes in giving these children intravenously two or three times a week from 50 to 100 cc of whole blood from nonrheumatic persons past 35 years of age. I am not sure that they have been helped, although some seem to have benefited. If I had youngsters with rheumatic fever I should send them to New Mexico or Arizona.

DR M I SHAPIRO, Minneapolis. We have had a similar experience with our rheumatic patients at the Lymanhurst Convalescent Home in Minneapolis. A number of our patients have died soon after the inception of the rheumatic infection and, in some instances, died with congestive failure. However, it has been our experience that congestive failure is not common and that when it does appear it is relatively mild in this group of rheumatic patients who die young. These patients who die with congestive failure have a combination of a chronic valvular defect plus active carditis. Patients who have acute

carditis alone without valvular defect do not have congestive failure, they die rather because of toxemia. It is a question in my mind whether congestive failure due to chronic valvular defects of the heart should be included under the heading of "rheumatic fever." The question as to whether or not a patient has a persistent carditis is not always an easy one to answer. During the past month I have had under observation at Lymanhurst a patient who brings out the difficulties in settling this question. This 15 year old boy was admitted to the ward about three months ago, he gave a history of having sustained his first attack of rheumatic fever about seven months previously. When he was first admitted he had a high sedimentation rate, a low grade fever, a rapid pulse, in short, all the evidences of an active carditis. There was evidence of early mitral and aortic involvement. After three months of complete bed rest all clinical signs became normal. The patient began to gain weight and had a normal sedimentation rate, the heart rate was slower, and the murmurs remained the same. The patient's condition was considered quiescent and he was gradually permitted to be up and about. He had been on a full time hospital schedule including some outdoor activity for about a month during which time the sedimentation rate remained normal and all clinical signs indicated no active infection in his heart. At this time, however, the boy developed the signs of acute appendicitis and was referred to the Minneapolis General Hospital, where he was operated on and an acute gangrenous appendix removed. Unfortunately, the condition was complicated by a gas bacillus peritonitis, and the patient died in three days. On postmortem examination, there was found acute valvulitis involving the aortic mitral valves with no evidence of healing. In this instance all the clinical signs including the sedimentation rate did not give correct information with regard to the degree of activity in this patient's heart. Dr Jones's contribution will assist in making possible a final decision as to the effectiveness of a change in climate for rheumatic children. Since this experiment began I have had a number of instances in which rheumatic families in poor financial condition have denied themselves almost every necessity in order to be able to permit a child of theirs to live in Florida. As I considered the group of patients that Dr Jones reported on, it seemed to me that they were much like the rheumatic group we have in our own convalescent home, I could not notice much difference between this group that had been transported to Florida and our own patients. In spite of the fact that Dr Jones does not now have so favorable an opinion on the effectiveness of this type of treatment, I believe the experiment was fully justified, and I hope that it continues. The only way to prove this question is to transport at least a hundred rheumatic patients to some favorable subtropical climate and keep them there a minimum of five years. We have enough control patients in the North to be able to draw definite conclusions.

DR ARTHUR DEGRAFF, New York. Dr Bland has shown clearly the course of rheumatic heart disease in children. It should be emphasized again that the course of the disease is different when acquired at an early age than when acquired in adult life. There seems to be a definite trend toward a much shorter and more fulminating course when rheumatic heart disease begins in early childhood. I was interested to learn that the incidence of subacute bacterial endocarditis was 6 per cent in Dr Bland's group. That is about the same as has been found in adults. Apparently the susceptibility to this complication is not affected by age. A rather important difference between Dr Bland's group of children and our group of adults is the mode of termination. Only a small proportion of children died suddenly whereas in about 10 per cent of our adult group death occurred from embolism, infarction or thrombosis. The rarity of auricular fibrillation in children might in part but not entirely account for this, because 8 per cent of the adult group who did not have auricular fibrillation died suddenly. I should like to ask Dr Jones whether he believes from his own experience so far that children kept under good environmental conditions, properly supervised, such as they are at the House of the Good Samaritan, do not do as well as children sent to Florida.

DR HOMER T SWIFT, New York. The society is fortunate in having these two papers presented today. In Dr Stroud's

discussion the statement was made that a 50 per cent mortality rate was about the same as that encountered by him in the convalescent home he is conducting. In the 1,500 patients treated in the House of the Good Samaritan there were 300 deaths, which gives a rate of about 20 per cent, this seems surprisingly good and indicates a better prognosis than we are accustomed to give at the present time. Possibly these figures are weighted because of the inclusion of a large number of patients with chorea. Dr Emmet Holt always held that rheumatic children had a remarkable capacity for recovery, and this report supports such an opinion. The papers of Dr Jones and his co-workers raise at least two important points. 1. Do these observations settle the question so often asked by parents "Shall we take or send our rheumatic child South or West or keep it at home?" We can, at least, answer that such a procedure is not a panacea and that the child may suffer relapses in the supposedly favorable environment. From a statistical standpoint a more satisfactory answer could be obtained from observing several larger groups having rheumatic fever and rheumatic heart disease of comparable types and intensity. One treated in Florida away from frequent contact with persons having upper respiratory infection a condition frequent in Miami, another group in southern California, a third in Arizona or New Mexico, and possibly a fourth in the true tropics. Comparable studies are possible in rheumatic fever, just as they have been in tuberculosis and would probably lead to important therapeutic conclusions. 2. A theoretical question that is raised is that having to do with the etiology of rheumatic fever. A number of patients had relapsed with little evidence of preceding hemolytic streptococcus infection, and the several instances of severe rheumatic relapse following sunburn make it appear that trauma, both infectious and noninfectious, may play a role in inducing relapses, and it is possible that substances formed in traumatized tissues may have an important etiologic bearing.

DR MAY G WILSON, New York. It is well known that in the North the incidence of rheumatic fever is low in the summer season. I have found in a series of observations over a ten year period that the seasonal incidence of rheumatic fever in New York City ranges in summer between 1 and 4 per cent, as compared with an incidence of from 30 to 40 per cent in the spring and early winter months. The incidence of rheumatic fever in Florida would not be expected to exceed that of the summer incidence in the Northern states. Perhaps Dr Jones can give some comparable data. If climatic conditions are of importance in the occurrence of rheumatic fever, one might expect that in subtropical regions the observed course and severity of the disease would differ from that seen in the North. The observations reported concerned children who were transported during rheumatic activity and are therefore difficult to evaluate. The clinical improvement noted would seem to be comparable to that observed in convalescent homes in New York City. The series of subjects who were in Florida for a period of years constituted an older group, in which the tendency to recurrences is usually less. It is rather surprising to find such a high incidence of recurrences among this older aged group. The course of the disease in the first three decades in twenty representative rheumatic subjects shows that after puberty the incidence of recurrences is low (being 33 per cent for a total series of 225 subjects). During childhood the majority (87 per cent) of the children had one or more recurrences. Of importance are the varied number of years (from one to seven) of freedom from the recurrences in subjects living in the same environment throughout the period of observation. Before it can be said with any assurance that climate is an environmental factor of importance in this disease, it would seem advisable to transport children for successive years, at least until puberty. If it is found that the course of the disease is modified thereby, change of climate would be advisable for rheumatic children. I should like to ask Dr Jones whether he has any information as to the familial incidence of rheumatic fever in Florida. Is it as high as it is in the North? In some recent studies I have come to the conclusion that hereditary susceptibility would seem to determine the familial incidence of rheumatic fever. If the familial incidence in subtropical climates is found to be low, it would indicate that climate is an important environmental factor in this disease. It

might then be advisable for rheumatic families to live in the tropical climates. It has taken a great many years to accumulate data on the course of rheumatic heart disease in the North. I hope that Dr Jones and his associates will be able to continue their important investigations for many years.

DR W PAUL HOLBROOK, Tucson, Ariz. I should like to congratulate Dr Jones and his associates on presenting this interesting subject of transportation of these rheumatic fever children to Florida. Just what criteria were used in determining whether the case is quiescent? I have had a good deal of experience with this same problem in southern Arizona and my impression is that the incidence of recurrence is much lower than eleven reported recurrences out of twenty six patients that were transported to Florida. Such a study as Dr Wilson has suggested is under way with groups of rheumatic children coming to southern Arizona. At least fifty children have come under my observation in the last three years and there has been only one recurrence. Whether that proportion will hold through the entire series or not I do not know.

DR E STERLING NICHOL, Miami, Fla. Two years ago I presented a paper on this subject before this association. When Dr Jones showed his first data I was inclined to feel that the variation from my own figures probably came about because his figures were on hospital patients and my patients were in small homes, not hospitalized. However, when he told of the additional group of patients under private management, I was at a loss to explain the discrepancy between recurrences in his group and the recurrences noted in my experience. I have been interested in this problem for eleven years and during that period have watched about thirty-six children with rheumatic disease who migrated to Florida. There have been only four definite recurrences in Miami in this group of patients, and three deaths. With some exceptions this group were from poor families.

DR EDWARD F BLAND, Boston. I appreciate Dr Swift's calling attention to the lower mortality rate. Our mortality in a group of 1,000 children over a period of ten years is 24 per cent. Dr DeGraff called attention to the subacute bacterial endocarditis in a somewhat older group in which the incidence was roughly 6 per cent. In our younger group it was 6 per cent. So perhaps our impression that subacute bacterial endocarditis is relatively rare in the younger group is wrong.

DR T DUCKETT JONES, Boston. I should like to answer Dr Wilson's question. I think you will agree that in one family living in Florida there have been two instances of rheumatic fever. I do not know how to explain the difference between Dr Nichols' data and ours. Whether the fact that these patients went north has something to do with it, I cannot say. The statement that Dr Shapiro made bears out the observations in the convalescent homes. The question Dr DeGraff raised was whether I felt that the House of the Good Samaritan care was similar to that in Florida and Dr Swift's question as to whether I felt that the prognosis was altered are extremely difficult questions. I am not motivated by a desire to advertise any section of the country. The problem is that of rheumatic fever and the effect of climate on it. I would say that there is an annual variation in the control group in Boston and the group in Florida. Transportation to a subtropical climate may be logical from the point of view of study but not from active therapy. I do not believe that under the conditions of the experiment as carried out there is an extensive difference. I am not sure that the results would not be the same if the patients had remained in our section of the country. That is dodging the issue to some extent. I think that if I had a child of my own with rheumatic fever I would think a good deal before sending him away. I would not send him to a general hospital. I would send him to a small place where there would be good medical service. I do not think it is worth the economic stress to send children away. We know rheumatic fever occurs in sections of the world only two degrees from the actual tropics. It is discouraging. Further observations should be made on a group of patients living in this climate consistently and then compare the results with a more or less identical group in the subtropical regions.

(To be continued)

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1927 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

The Liver as the Commissariat of the Body—Mann believes that he has collected sufficient evidence to indicate the importance of the liver in the mechanism of maintaining a constant supply of utilizable food for the organism. Hepatic activity must be considered as a possibility in every phase of metabolism. Present knowledge of the subject is only a small percentage of what must be learned before all the intricate processes involved are fully understood. The liver can be considered as a large storage and manufacturing plant, constantly teeming with activity. Through its vast sinusoids, which are in intimate relationship with the multitude of hepatic cellular units, are transported the various materials on which the tissues of the body must rely for their source of energy, growth and repair, and for the necessities for maintaining the processes of life. Some of these substances are susceptible of being used directly by the tissue cells, and the liver only stores them during periods of plethora. Other substances are more crude and the liver transforms them into a utilizable form. The vital stream to and from the liver must persist, during dearth of material, bodily disease and hepatic impairment. Surely the liver can rightfully be called the provider of the body.

Vitamin C Nutrition in Pulmonary Tuberculosis—Martin and Heise endeavored to determine the value of cevitamic acid in pulmonary tuberculosis by studying 150 tuberculous patients and fifteen normal nontuberculous individuals. The state of vitamin C nutrition was determined by collecting twenty-four hour samples of urine. All patients and controls were on the regular sanatorium diet. The test dose of cevitamic acid was given intravenously in some instances and orally in others, both normal and tuberculous individuals being tested. The extent and activity of the tuberculous process was simultaneously determined by x-ray and sputum examination, sedimentation rates and in some instances tuberculin skin tests. No adequately controlled evidence on the effect of cevitamic acid therapy on the course of pulmonary tuberculosis was obtained. The impression gained from the study is that it

does improve the prognosis, but no definite evidence for this impression was obtained. The study demonstrates the existence of a hypovitaminosis C in a large majority of tuberculous patients, the degree of hypovitaminosis is shown to parallel the extent and activity of the tuberculous process. The demonstration of the intestinal tract of the tuberculous patient as a factor in this subnutrition would indicate a loss in the specific absorptive powers of the normal intestine for cevitamic acid. The intestinal flora might play a part. The successful treatment of certain hemorrhagic diseases by cevitamic acid has led to the treatment of hemorrhage in tuberculosis with vitamin C. But attempts to stop hemorrhage in tuberculosis by the intravenous administration of cevitamic acid were not successful. Eight attempts gave no positive results. Judging from previous experience, the conclusion was reached that the period over which the pulmonary hemorrhage extended was in many cases shortened, however, a larger series would be necessary to establish this point. Involvement of the adrenals has long been suggested as a complicating factor in tuberculosis and it would seem that hypovitaminosis C plays an important part. Four cases of advanced pulmonary tuberculosis treated with adrenal cortex extract showed no response, but this does not rule out a possible effect, as cevitamic acid therapy was not instituted at the same time. Healing of the tuberculous process is a process of fibrosis. That vitamin C is required for the maintenance of all connective tissues is well known. Therefore the necessity of the maintenance of optimal vitamin C nutrition in tuberculosis is obvious. Cevitamic acid applications have been used successfully to stimulate the formation of granulation tissue and hasten healing of surgical wounds. It would seem that in any disease accompanied by fever there is an increased demand for vitamin C, in tuberculosis it is doubly essential to promote fibrosis.

Etiology of Appendicitis—Connell believes that distinction between appendicitis alone, and perforation and peritonitis, is important. Appendicitis is considered as a result of the sequence of obstruction, distention, circulatory stasis and infection. Obstruction may be due to a foreign body (mucous plug, edema or neoplasm), stricture (stasis, angulation and deformity) and functional derangement (spasm). The effect of the first two factors in obstruction is quite obvious, but that of the last calls for elucidation. The striking difference in the ileocecal region from all other gastro intestinal situations is that the parasympathetic distribution is double, which permits the possibility of overinnervation or underinnervation. Sympathetic-parasympathetic imbalance is a possible cause of hypertonicity or hypotonicity at the ceco appendical juncture. The existence of a true sphincter (Gerlach's valve) at this point has been denied, but circular muscle and extrinsic and intrinsic nerve supply, the necessary ingredients, are present. It would seem entirely justifiable to assume that disturbance in autonomic nervous balance might cause spasm or hypertonicity of the neuromusculature at the appendiceocecal juncture which might help to answer the original question as to the why of the obstruction that caused a certain proportion of cases of appendicitis. It would seem probable that overparasympathetic or underparasympathetic innervation of the ileocecal region is due to variations in embryologic development.

Ketonic and Nonketonic Estrogens—Having worked out satisfactory methods for the quantitative separation of the ketonic from the nonketonic estrogen, Westerfeld and Doisy investigated the distribution of the two forms in ovaries and placenta and the transformations that occur after the administration of pure theelin or dihydrotheelin. Sow ovaries, from which the follicular liquor and corpora lutea had been removed, were extracted with boiling ethyl alcohol. Purification was effected by methods commonly used in their laboratory. On fractionation between ketonic and nonketonic estrogens it was found that a small but definite quantity of ketonic estrogen is present. This observation was confirmed by treatment with semicarbazid, which destroyed the estrogenic property of the ketone. By means of the same methods, the study of cows' ovaries gave no evidence of the existence of a ketonic form, thereby adding one more item to species differences observed in studies of the follicular hormone. The extract of ten human placentas was purified. On a per kilogram basis, the placenta contained about 800 rat units, of which approximately one fourth (200 rat units) was ketonic. Since theelin is the ketonic estrogen in human pregnancy urine, probably theelin occurs in the placenta. When dihydrotheelin is injected into a normal adult, a castrate or a castrate-hysterectomized monkey, from 30 to 45 per cent of the excreted estrogenic activity is ketonic. When theelin is injected into a normal adult, a castrate or a castrate-hysterectomized monkey, from 30 to 50 per cent of the excreted estrogenic activity is nonketonic. The evidence indicates that in the monkey the reaction between theelin and dihydrotheelin is reversible and that the ovaries and uterus are not essential for this transformation.

Excretion of Male Sex Hormones in Man—Koch's studies on normal men and women covered urine collections for from twenty-seven to forty-five consecutive days. The collections from men usually were pooled for three consecutive days. From the women two daily samples were received except during menstruation, when the excretions were pooled for the period. These urines were completely extracted, the androgenic and estrogenic active substances were separated from each other and assayed on capons and spayed rats respectively. In seven of the eight subjects the urine was hydrolyzed for two hours. In one male subject hydrolysis was limited to fifteen minutes, hence the greater yield of androgenic units in this individual. In both men and women marked daily fluctuations were observed in the urinary excretion of androgens and estrogens. The rates of excretion of the two activities bear no relation to each other. Only one of the normal men gave an indication of a cycle in the rate of excretion of androgenic substances. Although the daily variations for a given individual and for the group of four men are marked, the daily individual averages are remarkably constant, ranging from 63 to 68 international androgenic units. The averages for the estrogenic activity are also remarkably close, that is, from 9 to 12 micrograms of theelin daily. In the normal women the rate of excretion of androgens is also variable and of a high order, but distinctly lower than in men. The averages are

again relatively constant. The daily excretion of estrogen also varies considerably in normal women but tends to be higher than in men. There is good evidence of the periodic rise and fall in the excretion of estrogens in relation to menses. The excretion is lowest during menstruation. The daily averages range from 18 to 36 micrograms. In male castrates, exceedingly small amounts of sex hormones are found in the urine. In eunuchoids the excretions of sex hormones are distinctly lower than in normal individuals. In gynec mastia, no excess excretion of estrogens was observed. In virilism there is a tendency toward a lower excretion of estrogens with a normal or higher excretion of androgens. In cases of virilism with adrenal involvement, the excretion of androgens is exceedingly high.

Involuntary Melancholia—A number of months before the publication of Werner's work, Schube and his colleagues had started an investigation of the value of theelin in the treatment of involuntary melancholia, and in view of the remarkable results obtained by Werner and his associates they report their results in four men and six women. In none of the ten patients that they treated with theelin was there evidence of improvement in the mental condition. The mental and physical condition of three patients became definitely worse during the treatment, one patient died. One of the patients continued to grow worse until the treatment was discontinued and then gradually reverted to his original mental state. In another patient regular monthly periods were established after six weeks of treatment with theelin. There was no alteration in the mental condition. No changes were noted in the hair, the texture of the skin, the breasts or the genitalia of any patient. There was no change in the appetite or the sleep rhythm of any patient. In two there was a definite loss of weight and in one of these there was marked retention of urine during treatment, necessitating catheterization, this man also had uncontrollable diarrhea. The blood pressure, the pulse rate and the pulse pressure, the blood and the urinary studies remained unchanged in every case. The sedimentation rate of the blood was not altered materially. The cholesterol content of the blood showed marked but unexplainable fluctuations.

Chronic Polio myelitis (Polio myelopathy)—A case of chronic polio myelitis in a patient who had had a previous attack of acute polio myelitis is reported. Histologic studies leads Steegmann to the following conclusions: 1 Chronic polio myelitis is a form of progressive spinal muscular atrophy. 2 A previous attack of acute polio myelitis may predispose to the development of this disease. 3 The term chronic polio myelitis is a misnomer, for the disease is a chronic progressive noninflammatory degenerative process. In the case reported, the spinal cord showed shrinkage of the anterior horns at all levels, with chronic degenerative changes and loss of cells. This process was associated with pronounced gliosis of the anterior horns extending into the white matter, increased fibrosis and gliosis around the blood vessels, fibrosis and thickening of the leptomeninges and diffuse myelopathy due to swelling of the myelinated fibers of the spinal cord. The

changes were not accompanied by mobile or fixed products of degeneration. Theories of the pathogenesis of chronic poliomyelitis are reviewed. The disease is considered to be a primary degenerative process of the anterior horn cells. Theoretically, this is due to metabolic factors, which can depend in part on the effect of the secondary tissue reactions in interfering with normal cell metabolism.

Physiologic Availability of Fluids in Secondary Shock

—Davis studied the nature and mechanism of the response of normal animals and of animals in shock to water and electrolytes. In view of the fact that the central phenomenon of shock is an anoxemia, it was decided that the rate of oxygen consumption of the animal provided a more accurate picture of the effects of traumatic shock on the tissues. Determinations of the blood pressure level were made to serve as controls. The study seems to indicate the presence of certain physiologic and pathologic limitations to the free and equal distribution of fluids in the organism in shock. The introduction of fluid into the intact animal produces a dilution of the blood with subsequent diuresis. In secondary shock the normal reservoir action of the blood for fluids is lost, and fluid leaves the blood stream more rapidly than in the intact animal. The site of fluid loss is greatest in the region of trauma, so that relatively little transudation of fluid occurs into the peritoneum or into the alveoli of the lungs. Evidences of water imbibition are present in the central portions of the hepatic lobules. The production of a lowered rate of oxygen consumption by the administration of fluids in cases of secondary shock does not result from interference with the supply of available oxygen by pulmonary edema. The stimulant action of water on metabolism is exerted only so long as fluid is actually present within the circulatory system and seems to depend on the resultant increase of blood volume or blood flow. Removal of serum albumin and globulin and of blood cells by the intro-

duced fluid into the area of trauma and the peritoneal cavity diminishes the material available for the transportation of oxygen and leads to a still greater degree of oxygen want.

Treatment of Extensive Burns with Silver Nitrate and Methyl Rosaniline—Branch maintains that the method of treating burns reported approaches closely the "ideal" treatment. 1 There have been no deaths in cases in which the treatment has been used thus far, and there were only seven deaths in ninety-five cases in which this form of therapy was used during its development. 2 The period of pain and shock was very short. Toxemia did not develop as a serious threat. 3 The morbidity was greatly reduced, for the patients were turned about in a few hours and were urged to get up and about in a few days and to wait on and amuse themselves. 4 Grafting of skin was done in only one case. Measures for the general upbuilding of the patient were also carried out. The combination used was silver nitrate and methyl rosaniline. A 10 per cent solution of silver nitrate acted on the proteins of the serum exuding from the burned area to lay down immediately a milky white coagulum. This then took the place of tannic acid in coagulating the proteins and preventing the loss of body fluids. The methyl rosaniline stained this coagulum violet and aided in destroying and preventing infection. At the end of three weeks the second degree burns had all healed and the crust had cracked off. The third degree areas were still covered by the violet coagulum, but this was easily removed by bathing daily in brine and by the use of compresses. On soaking off the crust there were invariably enough epithelial islands beneath so that no grafting was necessary. After the coat was off, compresses soaked in cysteine hydrochloride, 1:200 solution, or compresses or gauze treated with scarlet red were used to stimulate epithelization of the denuded areas. Thus the period of pain and shock was practically eliminated. The amount of parenterally administered fluids necessary was greatly reduced. The following procedure is carried out: 1 A large dose of sedative is given. 2 The burned areas are washed with tincture of soft soap. 3 Debridement of the burn is done by merely breaking the blisters and removing the loose skin, and the area is washed with saline or boric acid solution. 4 The burn is sprayed at once with a 1 per cent aqueous solution of methyl rosaniline, and after three or four minutes the entire burned area is swabbed with a 10 per cent solution of silver nitrate. 5 The patient is placed in a burn tent at a temperature of 85 to 90 F. The area is resprayed with a 1 per cent solution of methyl rosaniline every fifteen minutes for about five times. After that the spray is used once or twice a day only if necessary. 6 Fluids are forced by mouth. 7 Hypodermoclysis of physiologic solution of sodium chloride is given every six or eight hours, as indicated by the patient's condition. 8 Fluids are given intravenously only if the temperature rises to 103 F. 9 Transfusion is done if necessary. 10 The patient is moved about as soon as the crust is established and is allowed to walk about as soon as the period of shock is over and if no signs of toxemia develop. 11 If any coagulum remains at the end of two and one-half or three weeks, it should be soaked off with brine or by compresses.

Circulatory Disturbances Inaugurated by Stimulation of Celiac Plexus—Recently, in a case in which a difficult cholecystectomy was performed, at the stage when operative manipulation was at a maximum, Burstein and Rovenstine observed an unusual phenomenon in the course of routine sphygmomanometry by the auscultation method. The blood pressure, which had remained constantly within normal limits with a difference of 60 mm of mercury between the systolic and the diastolic level suddenly became imperceptible for twenty minutes, although the peripheral pulse could still be palpated and was not materially altered in rate. At first, the mercury column being allowed to fall very slowly, a single beat was heard at about the level of the previous systolic pressure. Within a few minutes this single beat could not be obtained. When the operative manipulations had ceased, the normal auscultatory sounds were again obtained and at a level comparable to the previous determinations. Thereafter careful and frequent determinations of the blood pressure were made during all operations on the upper part of the abdomen. The phenomenon was soon obtained in the course of another chole-

cystectomy and during gastric resection. The patients had been given morphine and atropine preoperatively. To account for the circulatory disturbance noted, observations were made in the laboratory to determine the effects on the blood pressure curve obtained during intra-abdominal manipulations. Dogs were used for the experiments and it was found that stimulation of the celiac plexus when atropine sulfate has been administered previously produces a marked reduction in the pulse pressure with maintenance of the mean arterial blood pressure. Manipulations in the upper part of the abdominal cavity cause a reduction in the pulse pressure, especially when atropine sulfate has been given previously. Administration of physostigmine salicylate reduces the reflex.

*Cyanosis from Sulfanilamide E K Marshall Jr and E M Walz, Baltimore—p 140

Sulfanilamide Rash—In administering sulfanilamide to 180 patients both orally and parenterally, Schwentker and Gelman observed ten in whom a rash developed. In some cases it was recognizable as early as the third day of medication with sulfanilamide, in half of the cases it appeared between the tenth and fourteenth days. The eruption is distinctly morbilliform in character, is made up of maculopapular lesions slightly raised from the surrounding unaffected skin and is brownish red. Although it does not fade completely when pressure is applied, the blanching of the rash is considerably more marked than that seen with a typical measles eruption. Usually almost the entire surface of the body is affected, but in some cases the rash has been limited to the buttocks or to the legs. In some of the patients the eruption was seen on the palms of the hands and the soles of the feet, while the mucous membranes were apparently unaffected. There was no itching or other abnormal sensation at the site of the lesion. With discontinuance of sulfanilamide therapy the eruption fades rapidly and may disappear completely in forty-eight hours. If administration of the drug is resumed, the rash sometimes reappears faintly or in scattered areas but never assumes its former brilliance, and even this slight recrudescence gradually fades away. If the sulfanilamide treatment is not discontinued at the time of the primary rash, the eruption fades and disappears completely in about seventy-two hours.

Cyanosis from Sulfanilamide—Cyanosis of varying degree has been observed in patients undergoing intensive treatment with sulfanilamide. This cyanosis has been attributed to the presence of methemoglobinemia or sulfhemoglobinemia. Marshall and Walz have examined the blood from seven patients treated with sulfanilamide in an attempt to determine how far the oxygen carrying capacity of the blood is reduced in patients showing cyanosis. The oxygen carrying capacity was compared with the total iron pigment of blood. The conclusions

drawn from the data are that clinical cyanosis may be accompanied by any decrease in the oxygen carrying capacity of the blood and may occur without the presence of nonfunctional iron pigment within the errors of the methods employed. In two cases the figures indicated nonfunctional iron pigment. This nonfunctional iron pigment appears to be mainly methemoglobin. The possibility of methemoglobin being present in small amounts in the blood samples from the other cases cannot be disproved by the data. An average of the figures for the five instances in which neither cyanosis nor a dark color of the blood was present makes it unlikely that more than traces of methemoglobin were present in these bloods. Methemoglobin as the cause of the cyanosis and dark color of the blood can be eliminated in these patients and also probably as the only cause in the other two cases. The authors cannot deny that sulfhemoglobin as well as methemoglobin may occur under certain conditions after administration of sulfanilamide, but it seems clear that these abnormal iron pigments supply by no means the only, and probably not the main, explanation of the cyanosis so frequently encountered in using the drug.

Diet and Susceptibility to Damage by Aminopyrine—In the case of acute stomatitis and granulopenia of the dog the etiology is apparent it is the feeding of a particular diet. In acute granulopenia of man the pathologic changes are in certain respects similar to those of the dog but the cause is obscure although the administration of aminopyrine appears to play some part. It seemed possible then that a faulty diet might well be one factor at least which increased the suscep-

tibility to the toxic effect of aminopyrine. To substantiate this hypothesis Miller and Rhoads performed experiments which should prove that a dose of aminopyrine which is ineffective alone will cause a well defined disturbance of hematopoiesis when it is added to a diet (blacktongue diet) which is not by itself causative of symptoms. Paradoxically, the resulting disturbance of the circulating blood cells manifested itself in the erythrocytes rather than in the leukocytes. Anemia was brought about in dogs fed the blacktongue diet by the administration of amounts of aminopyrine which were without effect when given to dogs fed a normal diet. When sufficient amounts of the drug were administered to dogs fed a normal diet, an anemia did result. It was not as severe as that caused by administering aminopyrine to animals on the inadequate diet and was not associated with stomatitis. Ulceration of the oral and pharyngeal mucous membrane was a striking feature when administration of aminopyrine was combined with the inadequate diet. That the anemia and stomatitis were not due to the diet alone is clear from the fact that they occurred before they could be expected if only the special diet was fed. Moreover, they were more severe than are the changes of blacktongue and were of a somewhat different character. The absence of leukopenia was remarkable, particularly since it would have been expected from the histologic appearance of the bone marrow. From this fact it would appear that the action of aminopyrine is neither exactly that of benzene nor of the blacktongue diet alone. The histologic alterations of the bone marrow appeared to be similar to those described in a case of benzene poisoning by Andersen and also to those seen in several cases of aplastic anemia in which no history of exposure to benzene was available. The suggestion is advanced that the factor in the diet which makes it productive of blacktongue is an aromatic compound or that the diet renders the body incapable of detoxifying some aromatic compound, either present in the diet or a product of intrinsic metabolic formation.

Incidence of Pinworm Infestation in Boys—Bozicevich examined 230 boys for pinworm infestation. He used a swab (N I H swab) made essentially of cellulose film (cellophane) that is applied by means of a glass rod and then removed from the rod and examined directly on a slide under the microscope.

Only one swab examination was made for each boy. There were seventy-two positive for pinworms. The percentage is undoubtedly too low. Repeated examinations regularly increase the percentage of positive observations. The high incidence (31.3 per cent) in this group points to a generally unrecognized public health problem in the form of pinworm infestation. The study indicates that there is a more prevalent infestation in the population of Washington than is generally believed to be the case.

Changes in Bone Marrow in Diagnosis of Blood Dyscrasias—The procedure that Weller used in the study of the changes in the bone marrow in cases of blood dyscrasias consists in the insertion of an 18 gage spinal needle with stylet in place cephalad into the sternum at the angle of Louis. With an infiltration of a 5 per cent solution of procaine hydrochloride the patient feels only a sense of pressure until the needle has penetrated the outer layer of cortical bone. After the cortical layer of bone has been penetrated, the stylet is removed and the needle is pushed forward a distance of from 5 to 10 mm, then it is removed slowly, and the material within the lumen is spread out in a thin film on a glass slide. Practically all the patients in the study had an anemia. The changes which have been observed in the cells of the bone marrow in cases of pernicious anemia coincide with those described by previous observers. Thus far no case of aleukemic leukemia has been observed. Several patients with relatively low leukocyte counts have been studied and it has been found that the bone marrow in these cases is practically identical, from the cytologic standpoint, with the bone marrow in pernicious anemia. Of the two cases of myeloid leukemia in which simultaneous studies of both peripheral blood and bone marrow have been carried out, it was found in one that the changes in cells in the circulating blood were relatively slight, while the biopsy specimens of the bone marrow showed marked abnormalities. Two cases have satisfied the criteria for aplastic anemia, that is, there was no response to any form of medication. In these cases the bone marrow specimens showed a certain number of stem cells present, the total number being far below that found in an untreated case of pernicious anemia with an erythrocyte count at a corresponding level. The greatest help to be obtained from biopsies of the sternal marrow is information concerning the direction which therapeutic management of the case should take. If there is a megaloblastic hyperplasia of the cells of the bone marrow, liver extract is indicated. If the stem cells are few in number, little response to therapeutic measures is to be expected. If the cells of the bone marrow are abnormal in kinds and numbers, even though those in the circulating blood are relatively normal, the case deserves diagnosis and management as one of the neoplastic diseases (leukemia).

- *Sulfanilamide Must Be Used with Care Case Report H A Tarbell Newark—p 506

Sulfanilamide Must Be Used with Care—Tarbell warns that when sulfanilamide is being used the patient must follow the physician's directions explicitly. The author has had a patient—treated for gonococcal infection—who disregarded his physician's instructions. He was instructed after the third day to reduce the tablets (0.3 Gm) to three in twenty-four hours for four or five days more, and he was not seen again until seven days had elapsed, when he was found in bed and very sick. His temperature was 104.2 F, pulse 120, respiration 30, he was trembling, cyanosed, coughing a great deal, had had fifteen bowel movements that day and could not retain food without vomiting. He gave a history of disregarding the physician's directions and had taken 0.65 Gm of sulfanilamide every six hours regularly for ten days. He had also taken a dose of magnesium sulfate. The author reports this case with the hope of stimulating some state board regulation in the sale of sulfanilamide and to discourage its indiscriminate sale by druggists.

Clinical Observations on Xerophthalmia—Ayuyao has observed a total of 393 cases of xerophthalmia, from both the outpatient and the inpatient clinic of the Philippine General Hospital. The ages ranged from the first year of life to the early school year (7 years). Both sexes were affected. All the patients were children of parents belonging to the laboring class. These 393 cases constitute hardly 1 per cent of all the eye cases admitted to the hospital nevertheless. Ubaldo and Ayuyao found that 2.23 per cent of the blindness among Filipinos was caused by xerophthalmia. No cases have so far been observed in well-to-do families. It may be accompanied by both gastro intestinal and respiratory diseases. The disease responds readily to treatment consisting of nutritious food and vitamin A.

Cutaneous Hyperesthesia in Acute Salpingitis—In summarizing the impressions that Labate gained during his study of fifty-three cases of acute salpingitis, examined frequently for cutaneous hyperesthesia, he contends that 1 Cutaneous hyperesthesia may be entirely absent in the most acute case of salpingitis with elevation of erythrocyte sedimentation rate leukocytosis, pelvic peritonitis and severe pain. The patient may persistently fail to develop hyperesthesia. Thus the presence of cutaneous sensitiveness cannot be used in gauging the severity of the infection. Also the absence of cutaneous hyperesthesia has absolutely no negative value. However, in all patients having the initial attack of acute salpingitis, cutaneous hyperesthesia was elicited consistently, with the maximal area at either the spino-umbilical point or Ligats point. 2 Cutaneous hyperesthesia may be of fleeting and recurring character. It is difficult to explain this characteristic. It seems to bear no relation to increase or decrease in the severity of the infection. 3 The persistent type of hyperesthesia which is present on admission and remains throughout the acute phase of the disease is also encountered. Many times the maximal area of sensitiveness shifts. In this type, as the patient improves, the hyperalgesia will tend to disappear, only to recur again with an exacerbation of the disease. The total duration of cutaneous hyperesthesia in these patients varied between several to twenty-six days. 4 The maximal area of cutaneous hyperesthesia bears no relation to the maximal area of deep tenderness except in some cases. Therefore one must not predict the area of maximal hyperalgesia according to the location of maximal deep tenderness. 5 The total area of cutaneous hyperesthesia is variable rarely severe and determined only with the exercise of diligence. 6 A maximal area of cutaneous sensitiveness can always be determined.

Enterectomy in Hepatic Cirrhosis or Portal Obstruction with Ascites—Fuller and her associates cite a case of portal cirrhosis with ascites of a duration of more than twenty months treated by tapping, with no tendency toward diminution. After massive intestinal resection (enterectomy) the rate of ascitic accumulation was immediately approximately halved, and following a period of a gradual decrease of the ascitic fluid its formation ceased nine months after the operation. The patient has now been free from ascitic fluid for twenty-nine months. After operation the patient was permitted to follow his appetite as to any type and amount of food and liquid desired. His output of urine has averaged 1,300 cc daily. Though the patient has not suffered from constipation he has had no tendency to diarrhea, which is sometimes noted following massive enterectomy.

Postoperative Blood Lipids—Boyd studied the concentration of total lipid, neutral fat, total, ester and free cholesterol and phospholipid in the blood plasma and the erythrocytes in the blood of twenty-nine patients submitted to abdominal and extra-abdominal operations and complete abortion. The determinations were made before and from one to five times after operation. It was observed that ether anesthesia is the predominant factor responsible for changes in the concentration of plasma and erythrocytic lipids during the first day or so after operations. When operative procedures are accompanied by variations in body temperature, the latter may affect the concentration of blood lipids independently of the operations. The introduction of a toxic factor may also affect the values of the blood lipids apart from any concomitant surgical intervention. The removal of all or part of a structure, such as a fetus, thyroid or the placenta or presumably the prostate, may sufficiently alter lipid metabolism to affect the values of the blood lipids. Postoperative pulmonary edema is not a common condition, but when it occurs it may have a pronounced effect on the concentration of plasma lipids. In this condition the sudden concentration of plasma by removal of large amounts of fluid into the lungs and other structures produces a secondary polycythemia and an increase in the concentration of lipids in plasma. Postoperative cases in which no contributing factor can be established are usually found to have no significant alteration in the percentage of blood lipids, either those of the plasma or of the erythrocytes. This has been found in the present investigation to hold true for major as well as for minor operations, either inside or outside the abdomen. There

seems, therefore, no further justification for the use of the term "postoperative lipemia" or for the postulate that such a condition may exist and be due to surgical intervention itself.

Incidence of Pulmonary Embolism—Pilcher endeavored to determine whether pulmonary embolism has a seasonal or epidemic incidence. A request was sent out to the registrar general for the dates of death in all cases of fatal pulmonary embolism verified by postmortem during the years 1929 to 1934. The reply gave details of no more than thirty-five cases. It was then decided to attempt the collection of cases from the London teaching hospitals. Permission to make use of their postmortem records was granted by twelve hospitals. The material for analysis comprises 731 cases of fatal pulmonary embolism occurring in the years 1925 to 1934. During this period 911,215 patients were admitted and there were 46,562 deaths and 36,145 postmortem examinations. Having regard to the excess of deaths over postmortem examinations and the assumed incidence of undiagnosed or unconfirmed cases, the author concludes that every year at least 100 patients die of pulmonary embolism at the twelve hospitals studied. The records of these cases suggests that survival for many years might have been expected in more than half but for this accident. The distribution of the 731 cases over the 3,652 days of the decade was first studied and compared with the normal distribution found by calculating the Poisson series. No evidence has been found to support the impression that pulmonary embolism has any seasonal or epidemic incidence. In 573 cases there was a history of trauma, in 158 there was none. The predominance of traumatic cases is partly due to the high proportion of patients requiring surgical intervention that are admitted to the hospitals. A rough approximation shows an incidence of 0.105 per cent in surgical cases and 0.064 per cent in medical cases. It is suggested that a more important factor in etiology than the nature of the illness or trauma is immobilization of the patient. In traumatic cases the interval between trauma and death varies from one day to many weeks. The supposed primary thrombosis was found in the veins of the right leg more commonly than of the left in traumatic cases. There appears to be an association between right-sided injuries or operations and thrombosis in the veins of the right leg. This has not been observed, however, in cases of postoperative thrombosis not followed by fatal embolism. The age incidence reaches a maximum in the five years 55 to 59, both for traumatic and for nontraumatic cases.

Psychogenic Factor in Asthma—Strauss examined thirty unselected cases of asthma with a view to determining the absence or presence of 'nervous,' psychic or emotional factors in the asthmatic syndrome. Of the thirty cases the "nervous" element was found to be strongly present in sixteen cases, well represented in nine cases, feebly but definitely represented in four cases and undetected in only one case. 1 In its psychic

aspects, asthma may in certain cases be complex determined, 1 e, included in the group of the conversion hysterias 2 A person with the allergic diathesis, who is temperamentally a deviant from the conventional norm of his immediate social group, is likely to develop the asthmatic syndrome 3 An asthmatic subject is liable to make his asthma the center of his life, 1 e, to develop and cultivate an asthmatic personality. Such a person by the mechanism of what Kretschmer calls arbitrary reflex reinforcement can "turn on" his asthma on all possible occasions whenever it suits his unconscious or pre-conscious purposes 4 Allergic subjects who live under conditions of extreme emotional strain and stress are liable to exhibit the asthmatic syndrome 5 Asthma in an allergic subject may be part and parcel of a general state of anxiety, the affect, when the anxiety tension is very high, finding an autonomic reflex outlet. If these conclusions are justifiable, they suggest that psychotherapy, in the widest sense of the term, should reinforce physical methods of treatment, the form of psychotherapy being determined by the history of the case. Analytic psychotherapy would appear to be indicated in groups 1 and 5. Patients who fall into group 2 should benefit by a personality analysis, as opposed to an experiential analysis (vide Kretschmer) and taught how to accept and adapt themselves to their own temperamental patterns. In the case of group 4, it will sometimes prove possible by means of active intervention to modify the patient's environmental conditions. Patients who fall into group 3 should respond well to suggestive methods with or without hypnosis.

Lymphadenitis in Childhood—Brock and his colleagues support the view already put forward by several authors that in other instances of tuberculous mediastinal lymphadenitis the pulmonary changes are not due to some peculiar pneumonic reaction but can be explained entirely on the basis of atelectasis following bronchial obstruction due to the pressure of enlarged bronchial glands. They cite eight instances from which it is clear that gross secondary changes can occur in the lungs of children as a result of bronchial occlusion from tuberculous adenitis. In some cases there is no doubt that a fatal acute tuberculous bronchopneumonia may follow aspiration of caseous material into other parts of the bronchial tree if and when rupture occurs, in others there may be some peculiar pneumonic change, as seen by Cameron and De Navasquez in their case. On the other hand it is a surprising fact that no apparent harm may follow aspiration of the caseous material, as is shown by one of the authors' patients. Indeed, it seems possible that such an event may be followed by natural resolution and healing. If caseous material is discovered at bronchoscopy, it seems justifiable to remove it by gentle suction. When resolution is long delayed, it is reasonable to suppose that the prolonged bronchial stenosis with secondary atelectasis should be followed by the development of a total or unilateral bronchiectasis with a varying amount of secondary chronic pneumonia. No proved cases observed in childhood have been followed into adolescence or adult life and the development of a true bronchiectasis has not been demonstrated clinically and roentgenographically. On the contrary, it is not uncommon to see large calcified mediastinal glands with no sign of concomitant bronchiectasis. Such a gland must almost certainly be the cause of gross bronchial obstruction at one stage. It is however probable that actual infiltration and destruction of the bronchial wall is necessary before permanent secondary changes occur. Attempts should be made to follow into adult life cases of gross tuberculous mediastinal lymphadenitis in children so that more definite information can be obtained, for only in this way is it going to be possible to decide whether permanent bronchiectatic changes do commonly follow.

Transfusion of Stored Cadaver Blood—Shamov has used cadaver blood in forty-two cases. By the quantity and quality of the reactions after transfusion he found that transfusion of cadaver blood gave better results than the usual method. Reactions after transfusing cadaver blood are much rarer and are much less conspicuous. There were six reactions in very seriously ill patients in the forty-two cases, principally with diseases of the hematopoietic system. In no preceding series in his experience—a thousand transfusions in which citrated blood as well as the direct method was used—has the author observed so few reactions. The dead body can be exonerated from the suspicion of disease with much greater certainty. The supply is cheap, and with an efficient organization it is possible to have a stock of this blood in any quantity necessary for clinical needs. These advantages can be made use of in practice only with widespread and efficient organization for procuring the cadaver blood, and this is possible only in large centers. There is a strong prejudice in the majority of persons at the thought of transfusing cadaver blood into a living person. Such an attitude is a survival of primitive views about blood as the bearer of particular mystic properties. After a certain period man will overcome these prejudices as easily as the numerous others that have arisen during the history of the development of blood transfusion.

Prolongation of Action of Solution of Posterior Pituitary—During an investigation of factors influencing gastric secretion, Dodds and his co-workers found solution of posterior pituitary to have an inhibiting effect on glandular secretion. As this action is transitory, experiments have been conducted with various metallic salts in an attempt to prolong the inhibition. Groups of four 200 Gm male rats, fasted for twelve hours, were given 5 cc of water per hundred grams of body weight and simultaneously injected with the substance on trial. The urine excreted was collected and measured at regular intervals. Zinc salts caused a marked prolongation of activity, while cadmium and nickel have a similar and more powerful action. The action of histamine in stimulating gastric secretion also was prolonged by the presence of zinc.

 *Protein in Cerebrospinal Fluid Clinical Significance and Quantitative Determination G Phillips—p 179
 Gastro-Intestinal Symptoms of Hypoglycemia C Sippe—p 181

Protein in Cerebrospinal Fluid—In tabes and meningo-vascular syphilis the normal protein content of cerebrospinal fluid from 20 to 40 mg per hundred cubic centimeters is increased to from 30 to 80 mg, and at the same time there is a disproportionate increase in the globulin fraction. Phillips states that the protein content is increased in all meningeal infections, in septic meningitis and in tuberculous meningitis the protein may range from 50 to 150 or more mg per hundred cubic centimeters. In disseminated sclerosis also there is usually a slight increase in protein content. In cerebral abscess an increase in protein will be found in practically every case even when the abscess is deeply situated. The explanation of this

is probably the fact that an adequate centrifugal circulation is provided by the Virchow-Robin spaces to enable the discharge of protein from edematous areas of cerebral tissue surrounding the abscess. Even after apparently adequate surgical drainage of a cerebral abscess a guarded prognosis should be given while the protein remains at a level above that of high normal. Most intracranial neoplasms, particularly if they arise from the arachnoid and more particularly if they are situated in the posterior fossa will cause an increase in cerebrospinal fluid protein. All posterior fossa neoplasms except cholesteatoma, cause an increase in protein content, whether they are intracerebellar or extracerebellar in origin. This is due to the relatively smaller size of the cerebellum and its intimate contact with the fluid not only in the convexities but also in the fourth ventricle. Above the tentorium, protein increase is most likely to be caused by meningiomas or by any other cerebral growths which have arisen at or have grown into contact with the surface of the hemispheres or the ventricular ependyma. In growths in contact with the ventricles, the great bulk of protein is added to the cerebrospinal fluid after it passes out of the ventricular system into the subarachnoid spaces. Estimation of the protein in specimens of fluid taken from both lateral ventricles may be of localizing significance, since tumors in contact with one ventricle may produce an increased protein content in the fluid in that ventricle with little or no increase in the contralateral ventricle. In the third ventricle the well known colloid cyst does not cause any increase in protein, this knowledge may be of value in the differentiation of this condition from tumors in the same ventricle, particularly spongioblastoma.

Cooking and Antiscorbutic Value of Vegetables—Levy has applied the chemical method (titrating with indophenol) for estimating cevitamic acid in cooked vegetables. Specimens of the usual kinds of vegetables were taken from a large hospital and a mine native compound to find out to what extent the antiscorbutic activity is impaired by the culinary methods employed. The chemical procedure confirms the biologic method that the effect of cooking on vegetables is to bring about a loss in antiscorbutic value. The extent of the loss depends on various factors. 1 In all cases, with the single exception of unpeeled potatoes, a portion of the cevitamic acid is extracted by the boiling water, the larger the volume used, the greater the diffusion of the cevitamic acid. Much of this activity, however, is still available to the consumer, if the vegetable is boiled in the stew or soup for a short time. 2 Since the cevitamic acid is slowly extracted during boiling the longer the heating the greater is the loss. This effect is more apparent with cabbage than with potatoes presumably on account of the fact that the cells of leaf vegetables are more easily ruptured than in the case of tubers. 3 When vegetables are allowed to stand for a long time after boiling the cevitamic acid becomes oxidized fairly rapidly, presumably by atmospheric oxidation. This loss is over and above that experienced during the actual cooking. 4 When the vegetables were cooked in tinned or aluminum utensils the loss in activity did not increase. The amount and kind of metallic substances in the vegetables,

however, are important factors in destruction of their cevitamic acid content, since metals catalyze irreversible oxidation. The quantity of metal that is dissolved from the utensil during boiling would be exceedingly small compared with the amount actually present in the vegetable. 5 Solutions of cevitamic acid are rapidly destroyed by alkali even in the cold, and the biologic test shows that the addition of alkalis to boiling vegetables leads to rapid destruction of the antiscorbutic activity.

Roentgenologic Aspects of Interlobar Fissures—In making roentgenologic studies on patients with cardiac disorders, Roubier noted the great variety of roentgenograms of the pulmonary fissures of the patients with cardiac decompensation. He found that in patients with cardiac disorders inflammation of the pulmonary fissures exists almost exclusively on the right side. On the left side they are extremely rare. Moreover, inflammation is most frequent in the small fissure (horizontal fissure), whereas the large (oblique) fissure is rarely involved. When the oblique fissure is visible in the film, the horizontal fissure is visible also. In this connection the author points out that the roentgenograms were made from the front, in order to study the whole thorax and not to obtain information about fissural lesions. Consequently it is the horizontal fissure which is best visible in this position and its lesions are less likely to escape detection. The author discusses the pathogenesis and the significance of the inflammations of the pulmonary fissures in patients with cardiac disorders and reaches the conclusion that the fissural inflammations, which are so frequent in the advanced stage of cardiopathy are a roentgenologic manifestation of the propagation to the pleura of inflammatory lesions of the lung that has become involved in heart disease.

- *Sudden Death Without Apparent Cause in Pulmonary Tuberculosis Bonnamour Duplant and Ambre —p 471
*Diverticulum of Greater Curvature of Stomach with Signs of Subcardial Stenosis M Levrat and R Cade —p 481

Sudden Death in Pulmonary Tuberculosis—Bonnamour and his associates state that sudden death without apparent cause is occasionally observed in patients with pulmonary tuberculosis. They observed thirteen cases of sudden death among 3200 patients and among 920 fatalities. The causes are variable: there are lesions of the adrenals, tuberculous meningitis or acute tuberculous asphyxia. However the authors place especial emphasis on hepatic and renal lesions, which they observed in several cases. These lesions suggested sudden allergic reactions that were elicited either by a massive bacillary discharge or by soluble poisons and endotoxins of the tubercle bacilli.

Diverticulum of Stomach with Signs of Subcardial Stenosis—Levrat and Cade point out that diverticula of the greater curvature of the stomach were described first by Akerslund in 1923 and that the number of cases reported since has remained small. In the roentgenologic examination, these diverticula appear as small pockets on the posterior surface of the large curvature, visible only in the oblique position or after partial evacuation of the barium and only refilling at times in the recumbent position. The diverticula are frequently discovered by accident in the course of a roentgenologic examination, because, as regards the clinical aspects, they are often latent. In some cases, however, there are late irregular pains. In the case described by the authors, the diverticulum produced signs

of stenosis below the cardia, which disappeared under the x-ray screen in the positions that assured the evacuation of the diverticular pocket. The existence of these diverticula is explained by a throw-back to an embryonic condition. The treatment consists in the regular mechanical evacuation of the diverticular pocket and in measures against the inflammatory and spasmodic phenomena.

*Proteus Conjunctivitis and Contribution to Parinaud's Syndrome A. Zuccoli — p. 803

Proteus Conjunctivitis—Zuccoli reports the history of a woman, aged 53, who developed an acute swelling of the lids of the right eye. The anamnesis revealed that the patient had had for some time a secreting perianal fistula. The swelling of the lids was so severe that the right eye could not be opened. Moreover, the right cheek was swollen and the movement of the lower jaw was difficult. The disorder was diagnosed as Parinaud's conjunctivitis, although there was no destructive ulceration and necrosis of the conjunctiva. It is known that Parinaud's syndrome does not have a uniform etiology. Bacteriologic studies on the diseased conjunctiva disclosed *Bacillus proteus-vulgaris*. The conjunctivitis disappeared rapidly in response to nonspecific treatment, with moist compresses and instillation of a silver preparation. In order to demonstrate the pathogenicity of the proteus bacillus for the eye, animal experiments were made and it was found that mere instillation of proteus bacilli into the conjunctival sac may produce a suppurating conjunctivitis. By the subconjunctival injection of the bacillus a granulomatous conjunctivitis could be produced. Inoculation into the cornea, the anterior chamber and the vitreous body demonstrated a great pathogenicity of *Bacillus proteus* for the eyes of rabbits.

Blood Transfusion in Bronchopneumonia in Infants—Murano obtained satisfactory results from blood transfusion in eighteen of a group of twenty-six infants suffering from bronchopneumonia. The identity of the blood groups between patients and donors was previously established in all cases. The transfusions were made slowly in the vein of the elbow, and 15 or 20 cc of 10 per cent citrated blood was used for each transfusion. Besides transfusion the symptomatic treatment for bronchopneumonia was administered. In some cases satisfactory results were obtained with the first transfusion. In other cases two or three transfusions were given, one every other day. An intense reaction which is similar to that from a colloidoclastic shock follows the first transfusion in patients who follow an evolution to recovery. The reaction is less severe after the second and third transfusions and is poor in patients who are gravely ill. The reaction lasts for about two hours. It differs from that of shock from incompatibility of blood groups. Blood transfusion gives the best results in early uncomplicated forms of bronchopneumonia and also in toxic and infectious forms if it is given early in the development of

the disease. The results depend on the general condition of the patient when given the first transfusion. Blood transfusion stimulates the organic defenses and modifies the colloidal equilibrium of blood and tissues, it supplies the blood with proteins, ferments, vitamins and immunifacient substances.

- *Intestinal Trichomoniasis with Symptoms of Mucomembranous Enterocolitis P. De Muro — p. 425
Endocarditis from Nocardia Cases L. Alestra and M. Girolami — p. 441
Behavior of Blood Serum Proteins Following Repeated Bleeding B. Rubegni — p. 464

Intestinal Trichomoniasis with Mucomembranous Enterocolitis—According to De Muro, a review of the literature on clinical anatomopathologic and experimental studies shows that *Trichomonas hominis* has pathogenic properties similar to those of *Endamoeba histolytica*. It phagocytizes the erythrocytes and is the etiologic agent of certain diseases of several organs. Trichomoniasis with symptoms of mucomembranous enterocolitis is frequent. It may be of a simple febrile or emaciating clinical form. The author found twelve cases of the condition in adults in a span of about three years. In all cases there was the symptomatic triad of constipation, abdominal pain and elimination of mucous membranes. Constipation was moderate and sometimes there was pseudodiarhea. *Trichomonas* was identified from the feces or from fecal cultures. The microscopic study of the small pieces of the eliminated mucous membrane showed degeneration of the epithelial cells and presence of a few leukocytes and *Trichomonas*. The patients complained of pain at the iliac fossa and the transverse colon. Generally the patient had a humid tongue and an unpleasant breath. In three cases there was tumefaction of the abdomen. Five patients had a hypertrophic liver. There was hypochlorhydria in eight cases and hyperchlorhydria in one. In three cases chlorhydria was normal. In four there was eosinophilia. The author advises the examination of the feces for ten consecutive days because of the fact that the period in which the examination of the feces for the parasite may give negative results lasts for more than a week. The patients observed by the author were given a diet with pre-dominance of milk and greens without excessive dietetic restrictions. In all cases satisfactory results were attained from the administration of chiniofon or enterovioform by mouth. Detailed technic and dosage of the treatment are not given by the author.

Peculiar Case of Cleidocranial Dysostosis in Child Aged 7 Hildegard Winkler — p. 238

Clinical Aspects of Tuberculous Meningitis—Schlapobersky reports observations in sixty cases of tuberculous meningitis that came for observation at the university clinic in Bern and also cites reports from the literature. He found that tuberculous meningitis does not present a uniform clinical picture but may appear in many different forms. On the basis of the symptomatology he differentiates seven different forms: the classic type, the gastro-intestinal type, the narcoleptic type, the convulsive type (convulsions, chiefly of the tonicoclonic type), the hemiplegic type, the latent type and the type in which the consciousness is not impaired. Occasionally there are combinations of the different types. The temperature varies in different cases of tuberculous meningitis. The tuberculin test is usually positive (79 per cent of the author's cases). The changes in the cerebrospinal fluid vary. Increased pressure is a frequent change. Tubercle bacilli were discovered in 31.7 per cent of the author's cases. Other changes occurring with considerable frequency were positive Pandy and Nonne-Apptel tests, reduction in the sugar content and increase in the number of cells. The sedimentation speed was nearly always reduced. In 54 per cent of the cases it was possible to demonstrate the source of infection.

Elimination of Vitamin A in Human Feces —Wendt describes studies on the quantitative determination of vitamin A in the feces of healthy subjects with and without vitamin A tolerance tests and in the feces of patients with various disturbances in the processes of resorption. The feces that have been eliminated in twenty-four hours are rubbed up with anhydrous sodium sulfate and dried, then introduced several times into 96 per cent alcohol and left to stand over night. Passage through the suction filter is followed by boiling for thirty minutes with 25 per cent alcoholic solution of potassium hydroxide to effect saponification. After cooling the material is shaken several times with benzene. The benzene extracts are washed several times with distilled water until the reaction toward litmus is no longer alkaline. Then the benzene extract is dried for about twelve hours with sodium sulfate, filtered and condensed in a vacuum until dry, then combined with chloroform and again condensed. After that 10 cc of chloroform is added and to 0.2 cc of this mixture 1 cc of solution of antimony trichloride is added. The resulting blue coloration is subjected at once to colorimetry. Under the influence of the daily administration of three times twenty drops of a vitamin A preparation, the blue value of the feces increased at first only slightly, but between the twelfth and thirtieth day of the tolerance test it suddenly increased to several hundred or several thousand units. This seems to indicate that before an excess of vitamin A is eliminated in the feces the vitamin depots of the organism are filled and that the organism has a regulatory mechanism which prevents an excessive increase in the vitamin A content. In patients with considerable disturbances in the resorption (icterus, peritoneal carcinosis), the tolerance test with three times daily twenty drops of vitamin A preparation resulted at once in a severe blue reaction in the stools. The eliminated amount of vitamin A corresponded to the degree of impairment in the resorption.

Treatment of Hemorrhages in Essential Thrombopenia —Hildebrandt stresses the necessity of an examination of the blood in young girls with severe genital hemorrhages, for the hemorrhages may be caused by Werlhof's disease or by essential thrombopenia. After discussing the clinical aspects of thrombopenia the author evaluates the various therapeutic methods that have been recommended for it, pointing out that in recent years the research on vitamins has provided new therapeutic possibilities for the hemorrhagic diatheses. A preparation that contains vitamins A, B, C and D in combination with calcium phosphate has been used in essential thrombopenia successfully by some and without success by others. Still more recently the use of vitamin C has been recommended for the treatment of the hemorrhagic diathesis and several authors have produced favorable effects with vitamin C in essential thrombopenia with severe genital hemorrhages. He himself reports two such cases. The first patient, a girl, aged 18, had essential thrombopenia and genital hemorrhages. After various other methods, such as curettage, treatment with insulin, endocrine therapy and medicaments for the contraction of the uterus, had produced only temporary improvement, treatment with vitamin C and iron produced lasting results. The second patient was a woman aged 26. In this case also the genital hemorrhages as well as the petechial and mucosal bleedings responded to

treatment with vitamin C and iron. In the conclusion the author suggests that the favorable effect of vitamin C on hemorrhages and on the hemorrhagic diathesis is probably due to the fact that it reduces the vascular permeability.

Bone Lesions Caused by Overexertion in the Work Service M Detlef sen —p 1294

Surgical Treatment of Thyrotoxicoses —Kammerer stresses that in all severe cases of exophthalmic goiter, which develop rapidly, the postponement of the operation involves danger. If the internal treatment produces no essential improvement in the thyrotoxic symptoms, the preoperative iodine treatment according to Plummer should be instituted. Strict bed rest, quieting psychotherapy and, if necessary, sedatives are the first measures in the internal treatment of severe exophthalmic goiter. Animal proteins should be restricted, but carbohydrates should be given in relatively large amounts. If the metabolic rate increases in spite of this treatment, medication with iodine might be continued for a while after the operation. The thyrotoxicoses that develop during the menopause are often favorably influenced by irradiation of the hypophysis. In cases of exophthalmic goiter which are caused by iodine, irradiation is contraindicated. In mild cases of exophthalmic goiter, surgical intervention is unnecessary, for they either recover spontaneously or in response to internal measures.

Photosensitizing Substances and Cutaneous Tumors —Bungeler says that the occurrence of cutaneous carcinomas chiefly in the region of the face has given rise to the assumption that intensive exposure to sunlight is somehow concerned in the causation. However, since the same exposure to the rays of the sun produces cancers only in some persons, it was assumed that there are still other factors. In this connection the author points out that Kosanovics, in examining the urine of fourteen patients with facial carcinoma, regularly detected hematoporphyrin, which is not found in the urine of normal persons or of those in whom the carcinoma is in a different location. It has been assumed that the presence of hematoporphyrin in the urine is the manifestation of a constitutional anomaly on the basis of which the exposure to sunlight exerts its harmful effect. After reviewing the literature on this problem, the author describes his own experiments on the effect of photosensitizing substances on the development of cutaneous tumors. He produced photosensitization with eosin, hematoporphyrin and a fluid tar preparation. The experimental animals, white mice, were exposed to the sunlight for five or six hours each day. In a large number of animals it was demonstrated that the subcutaneous administration of the photosensitizing substances sensitizes the skin in such a manner that exposure to intense sunlight first produces inflammatory changes, which later are followed by atrophic and hypertrophic processes of the cutaneous epithelium and connective tissue and that these changes in turn lead to the formation of benign or malignant tumors. In control animals that were exposed only to sunlight but were not treated with photosensitizing substances there occasionally developed benign cutaneous neoplasms but never malignant neoplasms. Moreover, the percentage of animals developing tumors was much smaller in the control group than in the group that had been sensitized. Thus it cannot be denied that photosensitizing substances play a part in the development of cutaneous tumors.

Treatment of Serious Bone Fractures R Demel—p 1206

Prevention of Puerperal Mastitis—Von Brucke maintains that keeping the nipple dry is of primary importance in the prevention of mastitis. In view of the drying effect of tannic acid, he decided to treat the nipples with a powder containing tannic acid and formaldehyde. This powder is non-toxic and its application to open wounds is painless, at the most producing a mild burning sensation. After nursing, the nipple is carefully cleaned with a damp cloth and dried. Then the tannic acid powder is dusted on. The tanning and hardening effect of the tannic acid preparation prevents the penetration of pathogenic micro-organisms to the deeper tissues and promotes the healing of existing rhagades under dry crusts. Great care is taken that during the intervals between nursing the breast is kept dry. If the nursing is unable to empty the breast, the pump is used and an absorptive cloth is applied to the breast. The nurslings never showed aversion against the breast that had been treated with the tannic acid preparation. In 1,200 women in whom the breasts were treated in this manner only one case of mastitis developed, and this was in a woman who had an extensive furunculosis.

*Results of Irradiation in Cancer of Os Uteri D den Hoed—p 4063

Results of Irradiation in Cancer of Os Uteri—Den Hoed concludes that the present technic of irradiation produces cure in from 50 to 60 per cent of the operable cases and of the cases that are on the borderline of operability and in about 20 per cent of the inoperable cases. Further improvement of the results may be expected chiefly from an earlier onset of the treatment, that is, during a more favorable stage of the cancer. This implies that an early diagnosis is important. It is suggested that early diagnosis will be promoted by the regular examination of the apparently healthy. Moreover, the great technical improvements obtained during recent years in the field of radiology suggest that the number of cures can be increased also by further refinements of the therapeutic methods.

Some Neurologic Problems in Pellagra Illuminated by Treatment with Ventriculin H P Stubbe Teglbjærg—p 841

Treatment of Pellagra with Stomach Preparations—Petri and his associates conclude that disturbances in gastric function of local or central origin are of decisive etiologic significance in pellagra. They found that removal of the stomach in young dogs and swine induced a chronic, fatal disease regarded as pellagra, with universal morphologic changes in the nervous system and corresponding clinical manifestations. Since these changes were resistant to oral treatment with vitamin B, but rapid improvement followed administration of neutralized stomach juice, the symptoms seem attributable to the loss of a probably specific gastric function. In some patients, whose pellagra and alcoholic polyneuritis were supposed due to a deficient stomach function, treatment with human stomach juice or pressed juice from swine stomach as the sole treatment led to marked improvement or clinical recovery. The authors state that six cases of pellagra which originated during depressive psychoses in spite of sufficient diet were cured by treatment with ventriculin; the treatment had no certain effect on the psychoses. In cases with achylia it is important to add

twenty drops of hydrochloric acid three times a day to the fluid in which the ventriculin is given. The manifest pellagra symptoms will usually disappear in two months at the most. Because of the similarity in the changes in the nervous system in pellagra and in pernicious anemia and because of the affinity of both disorders by ventriculin, the authors would identify neuropoietin (or perhaps the product formed by its cooperation) as the probable antipellagra factor. The favorable effect of therapy with stomach preparations in cases of polyneuritis associated with disorders in gastric function (Petri and Wanscher) is believed to point to the loss of a specific stomach function in these cases, like that lacking in pellagra.

Myelomatosis—Transbøl says that hyperproteinemia accompanies myelomatosis. The most commonly employed test that can disclose it is the sedimentation reaction. While the globulin reactions are valuable aids in diagnosis, sternal puncture is important for earlier and more certain recognition of the disorder. In the case described, in which no clinical symptoms except cachexia and anemia were present, no elimination of Bence Jones protein and no roentgenologic changes, myelomatosis was suspected because of the exceedingly high sedimentation reaction (140 mm) in connection with but slightly elevated temperature, and the diagnosis was established through sternal puncture. Examination of the serum proteins showed a total protein of 9.45 per cent (2.92 per cent albumin, 6.53 per cent globulin). While cases of myelomatosis with normal serum proteins and greatly accelerated sedimentation reaction are reported, failure of the sedimentation reaction must, on the whole, be expected in myelomatosis with normal serum proteins. In cases in which the hyperproteinemia seems inexplicably high, closer examination of the serum by one of the more specific reactions is indicated, the formol-gel reaction is the simplest of these. Bing adds two drops of formaldehyde to 1 cc of serum and notes whether at room temperature a gelatin ring forms within three hours, in most of his cases this occurred during the first half hour, in two cases not until after two hours and in the author's instance not until after two hours and forty minutes. The test is positive only in more marked hyperproteinemia, which appears preeminently in myelomatosis but is also seen in Bing and Neel's disease, Boeck's sarcoid, grave liver disturbances and occasionally chronic infections. Takata's reaction may be positive. Jersild diagnosed six cases by means of "auto checking" of the Wassermann reaction. The author considers x-ray examination an uncertain method in myelomatosis and examination for Bence Jones protein of diagnostic value. In many cases of myelomatosis there is renal injury demonstrable by functional tests and determination of the blood urea. In some cases uremia is the direct cause of death. The possibility of myelomatosis should be borne in mind in atypical cases of renal insufficiency and myelomatosis was established in six out of the twelve cases of anemia of uncertain genesis found by Spiller among 432 cases of anemia.

I THE PROBLEM OF THE PNEUMONIAS

It is well known that in our part of the world "pneumonia" is not only a very prevalent but a very deadly disease. The combined average lethal rate of the pneumonias is close to 25 per cent. As a cause of invalidism and death, the pneumonias outrank the communicable diseases of childhood. They occupy third place in the mortality bills of New York City, New York State and the United States death registration area and are preceded only by the diseases of the heart and by cancer. They take a very large toll among people of the most productive age groups. There are few prevalent acute conditions which have such a high mortality or are as expensive to treat.

Within the last decade the curative value of concentrated specific immune horse serum has been established for the pneumococcic pneumonias of type I and type II, and evidence is rapidly accumulating that it is also efficacious in types V, VII, VIII and XIV. The general introduction of specific serum therapy has been slow. The possible reasons for it are:

- 1 The lingering of the dictum that the disease is self limited
- 2 Hesitation on the part of general practitioners to employ serum intravenously
- 3 The difficulty in obtaining serums, and their high cost
- 4 Lack of facilities for the differentiation of pneumococci
- 5 Failure on the part of health authorities, except in New York, Massachusetts and several other communities, to recognize the communicable character of the pneumonias and to urge appropriations for the free distribution of the antipneumococcus serums

The Bureau of Laboratories of the New York City Health Department, the Rockefeller Institute and several of New York's hospitals, notably Bellevue and Harlem, have made very important contributions to the development of specific therapy for pneumonia.

II A BRIEF HISTORICAL RETROSPECT

It has been established that the etiologic factor of lobar pneumonia in man is the pneumococcus although

other micro-organisms are sometimes identified with true cases of lobar pneumonia. Table 1 gives the bacterial flora in lobar pneumonia on the basis of 2,000 cases.¹

It is impossible within the short space of this section to give a detailed history of the evolution of therapy with pneumonia serum. Only the highlights will be touched on.

To Weichselbaum is conceded the credit for having definitely established in 1886 the causal relation of the pneumococcus to lobar pneumonia. The discovery by Neufeld of the solubility of pneumococci in bile led to the method of differentiation between the pneumococcus and the streptococcus. Pioneering work in the utilization of immune serum in pneumonia was done by the Klemperers in 1892, followed by Eyre and Washbourn, and by Elser and Roper at the New York Hospital in 1909 and 1913.

In 1909 Neufeld and Haendel first demonstrated the existence of antigenically different types of pneumococci. They also noted that the protective action of the antipneumococcus serum in mice was limited to the homologous strain of pneumococcus. In the two papers that they published in 1910 they discussed the need of type determination for effective serum therapy. They gave an account of the results obtained by them in treatment of patients with intravenous injections of potent antipneumococcus horse serum. They called attention to the need of administering large doses to obtain beneficial results.²

In this country it was under the auspices of the Medical Commission for the Investigation of Acute Respiratory Diseases of the Department of Health of the City of New York that the earliest work on the pneumococcus began. This commission was organized at the suggestion of Hermann M. Biggs in 1904, and a special grant of \$10,000 for the work was made by the Board of Estimate and Apportionment. E. G. Janeway was the president, William Osler, vice president and T. Mitchell Prudden secretary, the other members being William H. Welch, L. Emmett Holt, Frank Billings, John H. Musser, Theobald Smith and Francis P. Kinnicutt. The cooperation of a number of outstanding bacteriologists and pathologists was secured under the leadership of Biggs, William H. Park and Anna Williams. Reports were first published in the *Journal of Experimental Medicine and Biology* in 1905 and in the *Journal of Infectious Diseases* in 1906 and 1907.

In part I of the report of the commission, published in 1905, there appeared a paper by Katherine R. Collins

1 Cecil R. L., Baldwin H. S. and Larsen N. P. Lobar Pneumonia. *Arch. Int. Med.* 40: 253 (Sept.) 1927.

of the Bureau of Laboratories of the City Department of Health in which the following conclusions were presented

1 Pneumococci, by reason of their agglutinating properties, exhibit a tendency to separate into numerous groups similar to streptococci

2 *Pneumococcus mucosus* forms a distinct and consistent variety. The production by it of common agglutinins for some pneumococci and the resistance of the agglutinins produced by it to absorption by the streptococcus indicate a nearer relation to the former than to the latter organism

Further contributions to the biology of the pneumococci were made by Dochez and Gillespie of the Rockefeller Institute in 1913 and by Dochez and Avery in 1915. Their studies showed that there were at least three distinct and fixed types of pneumococci, designated respectively as type I, type II and type III, which comprised about 80 per cent of all the strains of pneumococci encountered in patients with lobar pneumonia. The pneumococci which were found in the other patients were for the most part unrelated to one another and were designated as group IV.

This work led to extensive clinical studies with unconcentrated antipneumococcus type I serum at the Rockefeller Institute by Cole and Dochez (1913) and later by Avery, Chickering, Cole and Dochez (1917).

TABLE 1—*Bacterial Flora in Two Thousand Cases of Lobar Pneumonia*

<i>Streptococcus haemolyticus</i>	76	3.8
<i>Pneumobacillus of Friedländer</i>	8	0.4
<i>Haemophilus influenzae</i>	1	0.05
<i>Staphylococcus aureus</i>	2	0.1

In 1920 Cecil and Blake showed that monkeys inoculated with a fatal dose of pneumococcus type I could be protected with specific type I horse serum.

As a result of the influenza pandemic of 1917 and 1918 the Metropolitan Life Insurance Company appointed a commission known as the Influenza and Pneumonia Commission of the Metropolitan Life Insurance Company. This commission held its first meeting July 15, 1919. It consisted of Milton J. Rosenau, chairman, William H. Park, G. W. McCoy, W. H. Frost, E. O. Jordan, Lee K. Frankel and Augustus S. Knight, medical director of the Metropolitan Life Insurance Company. The commission is still in existence, with the same chairman but with a changed membership. During the year 1920 the work of the commission was limited to epidemiologic and immunologic studies of influenza. In the following year a series of studies on the prophylactic use of influenza vaccines was made and experiments were carried on in New York and Massachusetts with pneumonia vaccines. At that time it was found that the extracts of the pneumococcus had no better prophylactic virtues than the vaccines usually made.

The refinements in the production of the pneumococcus immune serum were due to a number of workers. New York City was the pioneer in this field, the first really practical method for concentrating a specific immune serum, namely, diphtheria antitoxin, having been devised in the Bureau of Laboratories of the Department of Health by Robert B. Gibson in 1905. Subsequently, various modifications and improvements were made by Banzhaf, also in the Bureau of Laboratories of the Department of Health.

In 1915 Gay and Chickering were the first to show that the immune bodies in pneumococcus serum could be separated by biologic methods. Further fundamental work along these lines was done by Huntoon. Though Huntoon's antibody solution possessed definite therapeutic value, it frequently caused severe and some times fatal reactions. It was used in the treatment of several hundred patients at Bellevue Hospital.

In 1924, working under Rosenau at Harvard University, Felton developed a concentrated antibody solution by precipitating the euglobulins with large quantities of distilled water. The production of Felton's serum was aided by a grant of \$10,000 for three years which was placed at the disposal of Dr. Park by Mr. Lucius N. Littauer, who, by subsequent grants, is said to have given the sum of \$120,000 toward the study of pneumonia. The value of Felton's serum was conclusively demonstrated at Bellevue Hospital by Cecil and Sutcliffe and by Cecil and Plummer and at Harlem Hospital by Bullock and Rosenbluth. At this time, with the aid of another grant by Mr. Littauer, the first effective anti-pneumococcus type II serum was produced at Otisville and refined by Felton. Its clinical value was demonstrated when it was used on the first, second or third day. Its efficacy in cases presenting bacteremia was proved by Baldwin at the New York Hospital.

In 1926 Georgia Cooper and her co-workers at the Bureau of Laboratories of the Department of Health began the publication of a series of studies on the different strains of pneumococci, which had been previously classified as group IV, and succeeded in resolving them into twenty-nine types, they obtained pure cultures and antisera for each type. In the words of Rosenau, "This is considered one of the outstanding pieces of work of the Metropolitan Influenza and Pneumonia Commission." As a result of these studies the species of pneumococcus is now divisible into thirty-two types, each designated by Roman numerals.⁴ Some of these types are more prevalent in adults, others in children.

In 1928, with the aid of funds given to New York University through Dr. Park, and in 1930, through funds given to Dr. Charles Hendee Smith by the Commonwealth Fund, and as the result of a study of pneumonias in children at Harlem Hospital through funds given Dr. Bullock by the Littauer Fund, types I, VI, XIV and XIX were recognized as the most common invaders of children. Further work in this field was financed by the Altman Foundation for the production and testing of serum for additional types that were associated with pneumonia in children.

In 1929 reports of the value of concentrated serum for the newer types began to be published. The clinical evaluation of the newly segregated types V, VII and VIII was largely the work of the Harlem Hospital workers, under the Littauer grant. This work was subsequently confirmed by the Boston City Hospital group.

At that time an appeal was presented to the Commonwealth Fund by the Massachusetts Department of Public Health for a pneumonia study and service. The clinicians who experimented with the use of the serum in Boston were unanimous in believing that the serum should be distributed, the product made more potent, the cost lowered and reliable data obtained on the dosage required if the benefits to be derived from the antipneumococcus serum were to be enjoyed by all.

4 Some of the types are so closely related that the question has arisen whether they should be continued as separate entities. This applies particularly to type XXXI which is being classified with type XI and to type XXX which is now being classified with type XI.

those who stood in need of it. The Commonwealth Fund made the first grant in 1930, with the expectation that the demonstration would continue for five years. An advisory committee, under the chairmanship of Dr. George H. Bigelow, then commissioner of health of the state of Massachusetts, was organized, and Dr. Roderick Heffron became the executive who carried on the field work. The demonstration had a twofold objective: "the evaluation of pneumonia serum under the conditions of the general practice of medicine, and the development of plans for the distribution of this serum for the treatment of those patients who might reasonably be expected to benefit from its use."⁵ It thus embraced problems of scientific research as well as of administrative procedure.

It is now recognized that the most effective use of serum depends on the administration of the required amount in the shortest possible time. This is practicable only when the serum is of high titer. Felton's concentrated horse serum permits larger doses to be administered in smaller bulk and more effectively, it simplifies the procedure and reduces the incidence of primary reactions and of serum sickness.

Experiments are now being conducted by Goodner, Horsfall and McLeod at the Rockefeller Institute with unconcentrated but processed rabbit serum, and at Harlem Hospital under the direction of Bullowa with concentrated rabbit serum. Their limited experience to date indicates that rabbit immune serums have definite biologic advantages over horse immune serums.

III DEVELOPMENT OF THE RAPID METHOD OF PNEUMOCOCCUS TYPE DETERMINATION

In view of the importance of early recognition of the type of pneumococcal infection for successful therapy, the development of the technic of rapid type determination from the sputum is an important milestone in the evolution of the specific treatment of pneumonias. The pioneer work in this field was done by Krumwiede and Noble of the Bureau of Laboratories of the New York City Department of Health, who in 1918 worked out a method whereby they were able to differentiate the types from the sputum within a comparatively short period of time, its reliability was not established. Later Sabin devised the stained slide agglutination technic which saved time and material. The original methods of typing required considerable quantities of mouse peritoneal exudate for the agglutination tests.

Although Neufeld had described in 1902 the specific capsule swelling reaction, occurring when the pneumococci are acted on by the homologous immune serum, he appears not to have recognized its applicability to typing until nearly thirty years later. In 1931, in a study with Etlinger-Tulczynska,⁶ he described the reaction again and in a footnote stated that it was a convenient method for determining types of pneumococci. Credit for introducing the Neufeld swelling reaction for direct typing of sputum in Great Britain goes to Armstrong⁷ of St. Bartholomew's Hospital, and to Logan and Smeall⁸ of the Royal Infirmary of Edinburgh, who reported it simultaneously in the *British Medical Journal* of Jan. 30, 1932. It was introduced in this country in 1932 by Goodner at the Hospital of the Rockefeller Institute and was first described

here by Sabin⁹ early in 1933, after a test of it in 100 cases at Bellevue Hospital. In 1934 Beckler and MacLeod¹⁰ reported on the use of the method at the Bacteriological Laboratory of the Massachusetts Department of Public Health in 760 specimens of sputum over a period of sixteen months. At a meeting of the American Public Health Association in Pasadena, Calif., Sept. 3, 1934, Cooper and Walter¹¹ reported on the reliability of the Neufeld reaction as ascertained in the tests made at the Bureau of Laboratories of the Department of Health in New York City. Bullowa established the accuracy of the Neufeld method by direct cultures from the lung and blood.

IV PNEUMONIA PREVALENCE IN NEW YORK CITY

Although pneumonia has been a reportable disease in New York City for many years, the health department figures fall by a considerable margin to reflect the true number of cases of pneumonia in the city. An approximation of the divergence can be obtained by a comparison of the 16,972 reported cases of pneumonia in the year 1933, with the 20,163 patients with pneumonia known to have been discharged from the hospitals in that year. This discrepancy becomes even wider when it is realized that not all the hospitals in the city were included in the study, nor were institutions other than hospitals. The prevalence of the pneumonias can therefore be only approximated from the mortality rate. The total number of deaths from pneumonia has been decreasing annually since 1931, except for a slight upswing in 1936. During the last six years the number of deaths from pneumonia in New York City varied between 6,400 and 9,200. The average for the last three years has been 6,500 deaths. Assuming a case fatality rate of 25 per cent, the average number of cases of pneumonia during the last few years has been 26,000 per annum. There are no statistics to indicate how many of these pneumonias were of pneumococcus origin, but, assuming that 95 per cent of the lobar pneumonias and 75 per cent of the bronchopneumonias were of this etiology, the total pneumococcal infections numbered 22,000. When the very young and the very old are eliminated, it is safe to say that about 10,000 patients would be benefited by specific serum therapy. This figure should be borne in mind when plans are laid for the supply of antipneumococcus serum for New York City.

V TYPE INCIDENCE IN PNEUMOCOCCIC PNEUMONIAS

Many epidemiologic studies have been made of the types of pneumococcus found in patients ill with pneumonia. Considerable variations in the percentage distribution of the prevalent types have been observed. The latest study available is that of Bullowa and Wilcox,¹² which analyzes the distribution of the pneumococcus types and their variations in incidence and mortality for adults and children on the basis of 3,371 cases treated at Harlem Hospital from July 1, 1928, to June 30, 1936. This study shows that among adults there are considerable variations in the several types of pneumonia from year to year, that type I is consistently the most prevalent, followed by types III and VIII, although in the year 1934-1935 type V was next in prevalence to type I, and in 1935-1936 type VII took

that place. The conclusion drawn from this study is that the endemic pneumonias are a series of diseases which vary in occurrence from year to year and from month to month and that further studies of this character are needed to determine whether the specific types of pneumonia have individual cycles. The study also shows that there is a marked difference in the types of pneumonia found in children and in adults living in the same community.

The variation in the prevalence of the pneumococcus types from year to year makes it difficult for the health laboratories always to have adequate amounts of the different immune serums available to meet changing conditions.

VI ORGANIZATION OF PNEUMONIA CONTROL IN MASSACHUSETTS AND NEW YORK STATE

The modern practical application of the antipneumococcus serum had its birth in New York City. As far back as 1911 the Research Laboratory of the Department of Health began the production and limited distribution of a polyvalent antipneumococcus serum made from strains prevalent at that time.

Four years later the Division of Laboratories and Research of the New York State Department of Health prepared type I specific antipneumococcus serum for general distribution, and in 1917 sputum typing was added to the list of procedures required for qualification of approved public health laboratories rendering such service.¹³

In 1917 the Massachusetts Department of Health likewise undertook the production and distribution of pneumonia serum. The difficulties associated with the administration of unconcentrated serum and the frequency of severe serum reactions were responsible for the slow adoption of this mode of therapy. The intensive five year pneumonia study and demonstration carried on in Massachusetts from 1931 to the end of 1935, with the financial aid of the Commonwealth Fund, paved the way for an effective plan of administrative organization.

In the fall of 1935 the New York State Department of Health undertook to organize a comprehensive pneumonia control program embracing not only the production and distribution of concentrated antipneumococcus serum and the expansion of available laboratory facilities but also active participation in graduate professional information, in lay education, in the expansion of public health nursing service to pneumonia patients, and in research on the epidemiology of pneumonia and the evolution of more adequate means for its control. This program was undertaken with the close cooperation of the state medical society and the New York State Association of Public Health Laboratories, with financial aid from the Metropolitan Life Insurance Company and the Commonwealth Fund.

In Massachusetts the serum for type I and type II pneumonia is being produced for general distribution through a system of so-called laboratory supply stations. There are seventy-two such stations scattered throughout the state. Thus far only concentrated serum type I and type II are available to all physicians in the state. No charge is made for serum, regardless of the financial condition of the patient. Preparations are being made for distribution also of the therapeutic serums for infections of types V, VII and VIII. This likewise is to be furnished without charge. In the dis-

tribution centers the Neufeld method of typing is used almost exclusively. In a few instances the Sabin slide agglutination method is employed, either alone or in conjunction with the Neufeld method.

In order to conserve the available serum and to make it go as far as possible, two restrictions are being observed. No serum is given until the laboratory report indicates that the patient for whom it is requested is suffering from type I or type II infection, and then only for patients who have been ill for not more than four days. Physicians are requested to sign cards to this effect. Physicians who have received serums are expected to furnish the department of health with information concerning the patient after determination of the case. According to official report the two restrictions mentioned have encountered little criticism although it would seem that it is very difficult to determine precisely the duration of the pneumonia from onset to the time when the typing is done. The Massachusetts authorities are of the opinion that this time restriction aids in emphasizing the necessity of early typing and early treatment, which is so important in pneumonia. They admit that there are patients who after the fourth day of illness, might be benefited by the administration of serum, they are, however, prevented from changing the rule because of economic considerations. The distributing centers are authorized to issue serum in amounts of 60,000 units for type I and 100,000 units for type II. An additional 60,000 units for either type is permissible for the following three categories of patients:

(a) Maternity patients

(b) Patients with a positive blood culture of type I or type II pneumococci in their blood

(c) Patients whose temperature does not fall to 101 F or under within eighteen hours, or in whom the temperature, after having fallen, has again risen to or above 101 F in forty eight hours

In individual instances more than 60,000 units is given for the treatment of patients with persistent bacteremia or to pregnant women.

Arrangements are under way to allot larger amounts of serum for older patients, as it has been demonstrated that persons past middle age do not gain as much benefit from an average amount of serum as do younger persons.

In New York State the regulations differ somewhat from those of Massachusetts. Up to the beginning of this year only concentrated type I antipneumococcus serum was distributed. During the year 1936 approximately 5,700 vials of 20 cc each of concentrated type I were distributed. The 20 cc vials of type I contain 25,000 therapeutic units. Type II is put up in 24 cc vials, containing 20,000 units, and its distribution began on Dec. 30, 1936.

The serums are distributed through laboratory supply stations. There are 106 of these for the distribution of type I serum and thirty-four for type II serum. The number of the latter will be increased as the need is demonstrated and the supply of serum becomes sufficient to meet increased demands.

In New York State, as in Massachusetts, the serum is given away entirely free to all classes of patients, but there is no restriction as to time limit for administration. It is left entirely to the physician's discretion. He is, however, requested to fill out a form giving certain fundamental data in order to obtain the serum. In New York State the minimum dose is

¹³ Rogers E. S. Control of Pneumococcus Pneumonia. *Am J Pub Health* 27: 133 (Feb) 1937

recommended is considerably higher than that in Massachusetts, 100,000 units for type I cases and 160,000 for type II cases

VII SERUM PRODUCTION IN NEW YORK CITY

The New York City Health Department Bureau of Laboratories has been producing and distributing antipneumococcus serum for eleven of the more prevalent types. Table 2 gives the statistics of production of the various types during the years 1935 and 1936 in terms of vials.

The production of effective serums for the different types of pneumonia is not a simple matter. Horses must be immunized over an average period of almost fifteen months to develop antibody content of sufficient potency, some horses respond better than others. During the past few years the Bureau of Laboratories has maintained at Otisville an average of about forty horses for antipneumococcus serum. Part of the work involved in the process of concentration of the serum is done in New York City.

During the past year the Bureau of Laboratories of the Department of Health produced \$85,000 worth of antipneumococcus serum. It is estimated that each horse produces about \$2,000 worth of serum a year. These figures are based on the actual cost of production and are the same as those of the Massachusetts State Health Department Laboratory, namely, 35 cents per thousand units of concentrated serum, type I and type II. The cost varies somewhat with the type and whether the serum is monovalent or bivalent. For practical purposes, 35 cents per thousand units is a basic figure. Assuming the average therapeutic dose to consist of 100,000 units, the average cost of serum per patient is \$35.

In planning for the future health department authorities must determine the extent to which the city is ready to make available this life-saving remedy to all those in the population who are unfortunate enough to develop the disease and are unable to purchase the serum from commercial laboratories.

It is the opinion of this committee that in view of the communicable character of the pneumococcic infections and their mode of spread through congestion in places of work, public conveyances, schools and the like, the city should provide this serum on the same basis as it provides all other biologic products—serums, antitoxins, toxoids and vaccines.

The cost of community provision of antipneumococcus serum can readily be established if the demand is forecast. In part IV of this report it has been estimated that on the average 10,000 persons in New York City may be in need of serum during the year. In view of the slowness with which this specific serum therapy has been adopted, it is unlikely that a maximum demand will develop during the next year. It is more likely that the demand may not exceed the requirements of 5,000 persons. On the basis of \$35 as the average cost, the expenditure for serum which the city would have to incur would be \$175,000. It is possible that the demand in the future may exceed this estimate. In the opinion of this committee, it is advisable for the city to plan for the increased production of the serum rather than depend on the supply from commercial laboratories. In view of the experiments with rabbit serum, it is possible that, in the future, most if not all of the antipneumococcus serum may be produced in rabbits. This may decrease the cost.

VIII FACILITIES FOR CLINICAL CONSULTATION AND FOR TYPING

The successful administration of serum is a highly technical procedure requiring expert knowledge. Advice is often asked of the Bureau of Laboratories concerning technical procedures and no one with the necessary clinical experience and time is as yet available to render the required service. It is the opinion of the committee that a consulting service should be established similar to that provided by the laboratory in connection with meningitis and other communicable diseases of the central nervous system. It should be headed by a physician well trained in the knowledge and technique of serum therapy. A physician of this character should command a salary commensurate with the chiefs of other clinical services in the department of health. In addition, the health department should make arrangements with a number of men located in various districts of the city who are well known for their competence in this field and who would be willing to respond to calls for consultation service at moderate fees which the

‡ Available only during part of period.

city would be able to pay. It has been estimated that, for a time at least, in Greater New York about ten such men would be required to answer the emergency calls. The cost of such a consulting service, exclusive of the salary of the supervisor, would probably not exceed \$10,000.

As has already been stated, the effectiveness of serum therapy depends on its early administration. Facilities should be provided for quick diagnostic laboratory service. It is suggested that at least one laboratory be established in every borough for type determination, these laboratories to be centrally located and available daily to all physicians from 10 a m to 6 p m or later. In view of the fact that such diagnostic laboratory work is sometimes needed during the night, it is recommended that one of the laboratories be maintained throughout the night. Each laboratory would require two technicians. The committee therefore recommends that provision be made for fourteen technicians (two for each of the six typing stations and two to act as substitutes). The average salary of a technician is about \$1 000 a year. This would add to the budget about \$14 000 annually. Not all of this sum should be

charged to pneumonia, because during the months when pneumonia is not prevalent these technicians would be assigned to other work in the Bureau of Laboratories, which is understaffed

IX THE PNEUMONIAS AS A PUBLIC HEALTH PROBLEM

Early recognition and early serum treatment are needed to check the spread of pneumonia. Treatment of the pneumonias requires the same aseptic technic that applies to other communicable diseases. The incidence and mortality of communicable diseases have been lowered by segregation in special hospitals. It is therefore recommended that pneumonia patients treated in hospitals be properly segregated and cubed.

In view of the emergency character of the pneumonias, the hospitals should consider pneumonia patients in the same category with acute surgical cases, from the standpoint both of immediate preferential admission and of emergency service, night or day, by responsible members of the clinical and the laboratory staffs.

X RECOMMENDATIONS¹⁴

1 During the next few years, departments of health should engage in a vigorous campaign against pneumonia. Special divisions of pneumonia service should be established under the guidance of properly qualified physicians.

2 Through the regular medical channels, physicians should be made cognizant of the fact that serum is life saving in certain types of pneumonia and that the particular type of pneumococcal infection from which the patient may be suffering should be determined at the earliest possible moment. Free facilities for the rapid determination of the type of infection should be made available in each community at all times, day and night.

3 Because of the communicable nature of the pneumonias, it is highly desirable that pneumonia patients in hospitals be segregated in cubicles and that a complete aseptic technic be followed.

4 Pneumonia patients should be considered in the same urgent category with emergency surgical cases. Certain physicians on the attending staff should be made responsible for the treatment of these patients and should be on call day and night, as is the custom in the surgical services.

5 In connection with the divisions of pneumonia service of health departments, a clinical consultation service should be established to aid physicians in the administration of serum therapy and in the taking of specimens of blood and sputum for bacteriologic study.

6 In all instances of death from pneumonia, physicians should be requested to report the precise nature of the invading organism.

7 Concentrated serum for the prevailing types of pneumonia should be made available without cost to physicians requesting it, provided the type of pneumonia has been ascertained prior to the request for serum.

8 Control work of pneumonia and the production of therapeutic serums should not be allowed to interfere with the fundamental research activities of the laboratories.

9 The results obtained in New York and Massachusetts justify the appropriation of adequate funds to health departments for pneumonia control work and continued research.

PROGNOSIS OF DIVERTICULITIS AND DIVERTICULOSIS OF THE COLON

PHILIP W. BROWN, MD

AND

DAVID M. MARCLEY, MD

Fellow in Medicine, the Mayo Foundation

ROCHESTER, MINN.

Information is scanty as to what happens to patient who have diverticula of the colon. The following questions are frequently asked: How often is diverticulosis followed by diverticulitis? Have physicians been too strict or too casual in their attitude toward diverticulosis? Although the medical treatment of diverticulitis is rather simple, is it adequate? How many patients who have diverticulitis eventually undergo surgical treatment? What is the prognosis when surgical treatment is necessary? Is there enough evidence to warrant the assumption that there is more than a coincidental relationship between carcinoma of the colon and diverticulitis?

Those who are interested in a study of diverticulitis and diverticulosis are referred to a complete summary¹ that appeared last year. The present study was undertaken solely to evaluate the prognosis; it covers the decade from Jan. 1, 1919, to Jan. 1, 1929. Approximately 1,100 cases of diverticula of the colon were reviewed but this figure cannot be used to estimate the incidence of this condition. Naturally, all cases of diverticulitis were analyzed and follow-up data were sought in 376 cases but it seemed rather futile to persist with an analysis of the follow-up data in all cases of diverticulosis. After the data were studied in the first 220 cases of diverticulosis the data in the remaining cases were discarded, as they did not show anything significant. The cases which were studied were divided into the following groups: Group 1 includes ninety-nine cases of diverticulitis in which the patients had been treated surgically before they came to the Mayo Clinic or were subjected to operation after they came to the clinic; group 2 includes 277 cases of diverticulitis in which medical treatment was employed, and group 3 includes 220 cases of diverticulosis.

Information as to the future course of the disease after the patients left the clinic was obtained by examination or by letter in 86 per cent of the cases.

Rankin and Brown,² W. J. Mayo,³ and Ochsner and Bagen,⁴ in three separate reports from the clinic, said that the incidence of diverticula of the colon is approximately 5.6 to 7 per cent. Spriggs and Marver⁵ found diverticula of the colon in 100 (10 per cent) of 1,000 consecutive cases in which roentgenologic examination of the gastro-intestinal tract was performed. In nine of the 100 cases the lesion was in the prediverticular stage. Diverticulitis was present in from 12 to 17 per cent of the cases of diverticulosis reported by Rankin and Brown, W. J. Mayo, and Ochsner and Bagen. The ratio of diverticulitis to diverticulosis is one to six or eight.

From the Division of Medicine, the Mayo Clinic. Read before the Section on Gastro-Enterology and Proctology at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 10, 1937.

⁵ Spriggs, E. I., and Marver, O. A. Intestinal Diverticula. *Q. J. Med.* 10: 1-34 (Oct.) 1925.

The type of treatment employed in cases of diverticulitis also is of interest. Surgical treatment was employed in forty-eight, or 21 per cent, of the 227 cases reported by Rankin and Brown. Operation was performed in ninety-nine, or 26 per cent, of the 376 cases included in the present report. It therefore would appear that surgical treatment would be required in one of every four or five cases of diverticulitis of the colon. However, as will be shown later, the results of this study do not justify the conclusion that diverticulitis will develop in approximately 15 per cent of cases of diverticulosis or that surgical treatment will be required in 20 per cent of cases of diverticulitis.

The age and sex of the patients in this series of cases are shown in table 1. The ratio of males to females was 1.6:1, in the cases in which surgical treatment was employed this ratio was 1.9:1 and in the cases in which medical treatment was employed the ratio was slightly more than 1.6:1. While the difference in the incidence among the two sexes is not great, it does indicate that diverticula occur more frequently among males than among females. In this connection it is interesting to note that among all patients who are seen at the clinic the ratio of males to females is 1.04:1.

In the 527 cases in which the weight of the patients was given, 297 patients were overweight, 180 were of normal weight and fifty were thin. A plump patient is more likely to have diverticula of the colon than is a thin patient, but leanness does not make patients immune to this condition.

The diverticula, as determined by roentgenologic examination, were situated in the sigmoid colon in 290 cases, the sigmoid colon and descending colon in 123 cases, the left half of the colon in forty-nine cases, the entire colon in forty-three cases, the cecum and ascending colon in five cases, the hepatic or splenic flexure in five cases, and the transverse colon in three cases. In forty-one cases the site of the involvement was not stated and in thirty-seven cases roentgenologic examination of the colon was not performed.

TABLE 1—Age and Sex of Patients with Diverticulitis and Diverticulosis of the Colon

Sex	Age Years					
	20-29	30-39	40-49	50-59	60-69	70-84
Males (367 or 61 per cent)*	0	18	63	146	109	31
Females (229 or 39 per cent)	1	8	41	100	69	10
Total (596)	1	26	104	246	178	41

* The ratio of males to females was 1.6:1.

Proctoscopic examination is of more value than may be thought. It not only enables the proctologist to determine the presence or absence of carcinoma of the rectum but may also enable him to see far enough into the rectosigmoid to diagnose an inflammatory disease and it may permit him to see the mouths of the diverticula. Proctoscopic examination was performed in 218 of the 596 cases. This procedure disclosed probable trouble in or above the rectosigmoid in fifty-two cases and enabled the proctologist to see the diverticula in twenty cases. It also reveals the length of the healthy bowel distal to the diseased segment. This information is helpful to the surgeon in cases in which he hopes to effect an anastomosis following resection.

SYMPTOMS

The symptoms in the three groups of cases are shown in table 2. Although the symptoms have been described in other articles, a few moot points may be of interest. Bleeding from the bowel occurs more frequently in cases of carcinoma of the colon than it does in cases of diverticulitis. In one case of diverticulitis of the sigmoid colon in which bleeding was severe, resection revealed that the hemorrhage was the result of an associated angioma. One may wonder why bleeding was not recorded in any of the cases in group 2. While

TABLE 2—Symptoms of Diverticulitis and Diverticulosis

Symptoms	Cases					
	Group 1		Group 2		Group 3	
	Num ber	Per cent	Num ber	Per cent	Num ber	Per cent

Obstructive symptoms	67	68	149	64		
Purulent rectal discharge		No data	9	3		
Fistula of bladder	15	15	3	1		

bleeding did occur in a few of these cases, careful scrutiny of the history and proctoscopic observations seemed to indicate that the bleeding was purely anorectal in origin.

Both Ochsner and Bagen, and Willard and Bockus said that bleeding occurred in 7 per cent of cases of diverticulitis and it is possible that we may have been overly critical in our interpretation of the cause of bleeding in this series of cases. Purulent discharge occurred in nine, or 3 per cent, of the cases in group 2. The discharge was blood tinged and resembled that which follows the rupture of a furuncle.

These cases possibly should have been included in the group of cases in which bleeding occurred. While all writers agree that bleeding may occur in diverticulitis of the colon, it is important that carcinoma of the colon should not be overlooked in cases in which there is bleeding from the bowel.

We agree with Willard and Bockus,⁶ who expressed the opinion that diverticula which appear harmless at the moment may have been or will be the seat of inflammation. However, as a basis for prognosis, the cases have been divided into the three groups, according to the nature of the lesions when the patients first came to the clinic. On this basis, no symptoms are held referable to diverticulosis. The symptom diarrhea, irrespective of any final diagnosis as to its etiology, seems to occur less frequently in cases of diverticulitis than it does in cases of diverticulosis, hence when it is known that there is inflammation of diverticula and yet diarrhea is uncommon, it would not seem logical to hold that diverticulosis is a possible reason for diarrhea, although this opinion occasionally is given to patients.

Stress has been laid on the obstructive phenomena of diverticulitis, but in a third of the cases inflammatory symptoms, such as pain, fever and leukocytosis, predominated and purulent discharges occasionally were present. The cases in which fistulas of the bladder occurred are especially noteworthy, as in twelve of the eighteen cases in which this complication occurred there was little or no evidence of obstructive symptoms, but the symptoms were chiefly referable to the neighboring

6 Willard J. H. and Bockus H. L. Clinical and Therapeutic Status of Cases of Colonic Diverticulosis Seen in Office Practice. *Am J Dig & Dis & Nutrition* 3: 580-585 (Oct.) 1936.

inflammation and the perforation into the bladder. In one of these cases cystostomy was performed, for the vesical lesion was thought to be a diverticulum of the bladder, but it was found to be a fistula which had resulted from the perforation of a diverticulum of the sigmoid colon. The presence of vesical symptoms plus a history of the passage of gas through the urethra is practically diagnostic of a fistula.

RELATIONSHIP OF DIVERTICULITIS AND CARCINOMA

The question of the relationship of diverticulitis and carcinoma is interesting, if only from the historical point of view, as the early development of the surgical treatment of diverticulitis was the result of the study of cases in which lesions which were thought to be carcinoma of the colon proved to be diverticulitis. The first instances of excision of the colon for diverticulitis during the life of the patient was reported in 1907 by W. J. Mayo, Wilson and Giffin.⁷ In a former report four instances of carcinoma were noted in 227 cases of diverticulitis, while in another report thirteen instances of carcinoma were noted in 208 cases of diverticulosis or diverticulitis. Data regarding the presence or absence of carcinoma have been obtained in eighty-eight of the

No data						11

cases in group 1, in 238 cases in group 2 and in 192 cases in group 3. Carcinoma of the intestine did not occur in any of the cases in group 1. In five of the cases in group 2 carcinoma developed after the patients left the clinic and there is a vague possibility that carcinoma of the intestine developed in three other cases in this group. In fifteen of the cases in group 3 (diverticulosis) the patients had carcinoma when they first came to the clinic or carcinoma developed after they left. There was no evidence of any direct connection between the diverticula in any of the cases. In six of the cases in group 3 the carcinoma occurred at sites where there were not any diverticula, and in six other cases in the same group, in which operation was performed for carcinoma of the rectosigmoid or sigmoid colon, there was no evidence of diverticulitis. In the five (or eight) cases in group 2 the information regarding the occurrence of carcinoma was obtained by letter, therefore we are unable to express any opinion regarding the relationship of carcinoma and diverticulitis in this group of cases. A segment of the colon, particularly the sigmoid colon, that is the site of diverticulitis may later be the site of carcinoma, but such an occurrence would seem to be chiefly a matter of chance.

RESULTS OF SURGICAL TREATMENT OF DIVERTICULITIS

Ninety-nine of 1,100 patients who had diverticula of the colon received surgical treatment for diverticulitis before or after they came to the clinic. This does not indicate that 9 per cent of patients who have diverticula

of the colon will require surgical treatment, it merely represents the percentage that happened to be encountered in a particular decade. We are unable to give any prognostic figures as to the possible development of diverticulitis or the number of patients who will require surgical treatment.

In twenty-five of the ninety-nine cases in group 1 surgical treatment had been employed before the patient came to the clinic. In eleven of these cases no further operation was indicated, but in the remaining eight cases in this group some type of operation was performed after the patients came to the clinic. Ten or 11 per cent, of these patients died in the hospital and four other patients died from two to four months after their dismissal from the hospital.

We endeavored to determine how many of the patients may have received some type of medical management before operation was performed. In fifty-four cases it appeared that the true condition either was not apparent or that the condition of the patient made it inadvisable to delay the operation, and there is little evidence that preliminary medical treatment was attempted in these cases. In thirty-six cases the patient had had one or many attacks before operation was performed and it is evident that some type of medical treatment was employed. Oddly enough, we have a record of only nine cases in which a definite medical regimen was employed prior to operation. In six of these cases operation was performed from one to eight months after the patients were first seen and in the remaining three cases the patients were not operated on until three, five and six years, respectively, after they first were observed. These observations and the fact that four of the 277 patients in group 2 were, or should have been, operated on seem to indicate that a certain inevitableness pursues some patients who have diverticulitis, in other words, it seems to be their fate that symptoms will be entirely absent, moderate or severe almost from the onset.

The results of treatment in the cases in group 1 are shown in table 3. It is beyond the scope of this paper to consider the surgical phases of diverticulitis. It is generally accepted that diverticulitis is a surgical problem in the presence of such complications as abscess or perforation. In the fifteen cases in which operation was performed because of perforation into the bladder three of the patients died after the operation and nine patients reported that they did not have any more trouble, no report was obtained in the remaining three cases. This complication obviously is a serious one, but the prognosis is favorable if the immediate risk can be surmounted.

Colostomy and subsequent closure of the colonic stoma may be successful in some cases of diverticulitis. This procedure was successful in four cases but failed in four cases in this series. An inflamed perforated diverticulum was excised and the colon closed immediately in six cases, the results were satisfactory in five of these cases but a fecal fistula persisted in the sixth case. A localized abscess was drained in eleven cases in eight of these cases recovery occurred without any other operation, but in the three other cases a fecal fistula persisted. In such cases it would seem as if a single diverticulum had perforated and resulted in an abscess. Resection of the involved segment of the colon was performed in forty-one cases. In the thirteen cases in which the resection was performed after a preliminary colostomy there were two deaths. There were three deaths in the twenty cases in which a Mikulicz type of

⁷ Mayo W. J., Wilson L. B. and Giffin H. Z. Acquired Diverticulitis of the Large Intestine. Surg. Gynec. & Obst. 5: 8-15 (July) 1907.

resection was performed and four deaths in the eight cases in which resection and anastomosis were performed at the same time

Thirty-six of the patients in group 1 are known to have died. Fourteen of these patients died at the clinic or in less than a year after they left the clinic. Their deaths were wholly or partially attributable to diverticulitis. The condition of the intestine of the patients who have lived for more than a year after leaving the clinic is of interest. Of the patients who have lived from one to five years, seven reported that the condition of their intestine was normal and one patient reported that it was not normal, three other patients are known to have died but we have no data as to the cause of their death. Of the patients who have lived from six to ten years, four reported that their intestinal condition was normal and one reported that it was not normal, three other patients are known to have died but the cause of their death is unknown. Of the patients who lived for from eleven to fifteen years, two reported that their intestinal condition was normal, another patient is known to have died but the cause of death is not known. It is presumptuous to assume that there was no intestinal trouble in the seven cases in which the cause of death is unknown, but it is probable that disease of the intestine was not a dominant problem.

If we omit the eleven cases in which the condition of the patient is not known and the seven cases in which the patients died of unknown causes, there will remain eighty-one cases which may be used to evaluate the results of surgical treatment. Thirty-three patients are still living and thirteen patients died, one or more years after operation, of unrelated causes, therefore it may be said that forty-six of the eighty-one patients were benefited by the operation. Sixteen patients died, immediately after operation or later, as a result of the disease and nineteen patients have continued to have more or less intestinal trouble, therefore surgical treatment was unsuccessful in thirty-five cases. Although the results of our observation suggest that in certain cases of diverticulitis the outcome is inevitable, that is either good or bad, in recent years a determined effort has been made to treat this condition by medical measures. However, if complications ensue, operation should not be delayed. The operation should be the safest procedure, which usually is a colostomy or incision of an abscess. The surgeon then should wait for the acute symptoms to subside before he attempts any other operative procedure.

RESULTS OF MEDICAL TREATMENT OF DIVERTICULITIS

The results of medical treatment, which was employed in 277 cases of diverticulitis (group 2) are shown in table 4. We like to point with pride to the 118 patients who reported that they were well, but the sixty-one patients who reported that they still had intestinal trouble and the fifty-nine patients who are known to have died are of especial interest.

We have made an effort to classify in the same group all patients who reported that they had a persistence of the intestinal trouble, regardless of whether the symptoms were very mild or occurred in the form of severe attacks which lasted for several days. The majority of patients who still had intestinal trouble said that they were able to live in comparative comfort if they were careful about their diet, if they took oil regularly or if they eliminated nuts and coarse foods

from their diet. By adhering to a definite regimen they have learned to minimize the frequency and severity of the attacks. Two patients who were operated on for diverticulitis several years after they left the clinic reported that they were well six and ten years respectively after the operations. One patient who was treated medically for several years finally was advised to submit to operation but refused, the patient died three months later. Another patient who refused operation at the clinic was operated on seven years after leaving the clinic, this patient died after the operation. It is significant that twenty-three of the sixty-one patients who reported that they still had more or less intestinal trouble have lived for eleven or more years since they first came to the clinic. They did not express any regret that they had not been operated on and they appeared satisfied with their condition.

Hence, in the cases in group 2, only two of the patients who are still living and two of the patients who are known to have died required surgical treatment because of the diverticulitis. We previously said that surgical treatment was employed in ninety-nine, or 26 per cent, of the cases of diverticulitis but an analysis

TABLE 4—Results of Medical Treatment in 277 Cases of
Diverticulitis (Group 2)

Results	Years Since Patients Were Admitted to the Clinic					Total
	1-5	5-10	10-15	15-20	20+

Unrelated deaths or cause of death unknown	21	20	7	1		49
No data						49

of the results obtained in the 277 cases in group 2 does not indicate that from 20 to 25 per cent of patients who have diverticulitis eventually will require surgical treatment. About the only conclusion that is warranted is that patients who have uncomplicated diverticulitis and who follow a medical regimen seldom require surgical treatment.

Of the fifty-nine cases in which death is known to have occurred, the cause of death and the condition of the bowel were not known in twenty cases and death was not related to the diverticulitis in twenty-nine cases. Two patients who were advised to submit to operation at the clinic died following operation which was performed elsewhere. One patient, aged 73 years, was so ill when he came to the clinic that operation was impossible, this patient died a month later. Seven other patients were operated on elsewhere for some intestinal lesion which was reported as "cancer" or obstruction but it is doubtful whether the operation was performed for diverticulitis in any of these cases. Of the fifty-nine patients who are known to have died, about a third (nineteen) had more or less intestinal trouble and a third (twenty) had little or no intestinal trouble in the remaining years of their life. In the remaining third of the fifty-nine cases, no information was obtained regarding the persistence of the diverticulitis.

In thirty-nine of the cases in group 2 we were unable to obtain any data regarding the condition of the patients after they left the clinic, twenty more patients are known to have died but it was impossible to obtain data regarding the intestinal condition after the patients left the clinic. If these fifty-nine cases are omitted, there will remain 218 cases which may be used to

evaluate the results of medical treatment. The results were satisfactory in 63 per cent and unsatisfactory in 37 per cent of these cases (table 4). We are attempting to be very critical, but three fourths of the patients who reported that treatment did not fully correct their intestinal condition have had relatively little intestinal trouble and have been able to perform their usual duties without serious handicap as far as the diverticulitis was concerned.

MEDICAL TREATMENT OF DIVERTICULITIS

Rest in bed is important, patients with severe diverticulitis should be kept in bed for at least three weeks. Nothing should be given by mouth for the first day or two, in order to rest the inflamed colon further. An adequate amount of fluid should be administered parenterally. The application of heat has proved beneficial. When available, short wave diathermy has proved very efficient. When this is applied over the affected region, two or three times daily, it seems actually "to melt" the inflammation. The Elliott treatment also may be used but it is less satisfactory for men than it is for women. The insertion of the tube into the rectum has proved uncomfortable in some cases, but when the bag is inserted into the vagina there is no distress and the heat penetrates into the sigmoid region. If diathermy or the

add to the bulk of the stools, plain agar agar is safe and a soft, bulky stool possibly may gently dilate a narrowed bowel. Many patients who have used liquid petrolatum and agar agar for years attribute their freedom from attacks of diverticulitis to this regimen and regulation of their diet. Drugs do not seem to be of value. Tincture of belladonna may be administered but we are doubtful whether it is of any value.

PROGNOSIS IN CASES OF DIVERTICULOSIS

As previously stated, more than 700 cases which were reviewed indicated that the diverticula were merely incidental observations. The first 220 cases were taken for a follow-up study. Possibly the inclusion of more cases would have changed the apparent conclusion, but this would seem doubtful. The results in these cases are shown in table 5.

The term "well" refers only to the question of any intestinal symptoms attributable to diverticulitis. In seven cases the cause of death is unknown. In the forty other cases in which death occurred there was one in which there is a possibility that diverticulitis developed and death followed operation nine years after the patient left the clinic. Hence, so far as this study permits conclusions, the probability of the later development of diverticulitis is remote. By no means should this suggest an indifferent, careless attitude toward the presence of diverticula, and one should not fail to caution these patients about their diet and bowel habits. It does indicate that one should not consider diverticulosis as a diagnosis of the cause of abdominal symptoms.

It may seem paradoxical to learn that of this group of 192 cases in which there are data there was only one instance and that one is not certain of diverticulitis. Certainly, when 139 patients lived six or more years without symptoms of diverticulitis one cannot justify a statement such as one of us (P. W. B.) previously made, namely, that diverticulitis will develop in 17 per cent of cases of diverticulosis.

Figures on the incidence of diverticula would seem correct, but, so far as this study permits conclusions, diverticulosis seems to remain as such. We are greatly perplexed and can give no explanation for the obvious fact that all diverticulitis must start from diverticula but that it develops only in some cases.

SUMMARY

Follow-up data were obtained in 86 per cent of a series of 596 cases of diverticulitis or diverticulosis. In a few cases of simple diverticulitis, complications may develop and require surgical treatment. Surgical treatment was employed in ninety-nine cases of diverticulitis, fifty-seven of the patients were cured and 43 per cent either continued to have intestinal trouble or died after the operation. A peculiar predestination seems to occur in cases of diverticulitis, symptoms may be entirely absent or they may be moderate or severe. It is impossible to say how many patients who have diverticulosis later will suffer from complicated or uncomplicated diverticulitis. Medical treatment of diverticulitis consists of rest, the application of heat, regulation of the diet and the oral administration of olive oil. In 63 per cent of cases this type of treatment was successful, but in 37 per cent of cases the results were only fair or poor. However, many of the latter group of patients were able to live in comparative comfort. The results of our observations confirm previous opinions that the relationship between diverticulitis and carcinoma of the colon probably is incidental rather than actual. In a

Elliott treatment cannot be used, electric pads or hot packs, which should not be too heavy, are always available and of value. While two-way rectal irrigations with hot physiologic solution of sodium chloride provide another valuable source of heat, such irrigations may prove irritating and increase the discomfort in some cases. As a rule, we prefer to use a small warm enema to cleanse the bowel. In the acute stages of the disease, retention enemas of warm olive oil, which are given while the patient is in the knee-chest position, are often very comforting and help to promote bowel movements. When the patients are thin and the number of calories is of no concern, the daily administration of 2 or 3 ounces (from 30 to 60 cc.) of olive oil may produce enough fatty residue to stimulate bowel movements. Liquid petrolatum has proved useful, the number of patients who say that small doses of this oil, administered daily, contribute to lessen their trouble far outnumber those who say that the oil acts as an irritant. When administered in small doses it rarely will cause irritation, leakage or pellet-like stools. As the acute stage of the disease subsides, food should be given orally, the diet at first should consist of fruit juices, rice, jello, arrowroot cookies and eggs, but it gradually should be increased to a normal sensible diet. It may be wise to give the patient vegetable purees in the beginning, but it is not necessary to continue such a diet indefinitely. Substances and foods that should be excluded from the diet are bran, whole wheat, popcorn, nuts, and berries which have large seeds. Early in the "bran fad" some patients who were allowed to eat bran were certain that it stimulated bowel movements, while others felt that it was an irritant. If one desires to

third of the cases of diverticulitis the symptoms are the result of inflammation and in two thirds of cases the symptoms are the result of obstruction and inflammation

ABSTRACT OF DISCUSSION

DR HENRI L BOCKUS, Philadelphia There is little in the literature in the way of follow-up studies over many years and I was particularly interested in the paper for that reason. Last year in collaboration with Dr John Willard I went over a group of our office cases. They represent a somewhat different type from the patients seen by Drs Brown and Marcle. In their group were a great many of the complicated cases, patients who went to the clinic because they were seriously ill and had to be operated on. Eight per cent of our office patients, having had barium sulfate enemas had pouches in the large bowel. The average age was 55 years. We encountered none under 30. In 50 per cent of our patients with barium enema studies we felt justified in making a diagnosis of irritable colon. It is rather fortunate that symptoms from the irritable colon and from appendicitis occur in the younger age groups. They are rather rare after the age of 55. I do not know what the authors meant when they said that only one or two of their patients had diverticulitis. I will agree that it is difficult to decide whether the symptoms are due to irritation of the pouches or whether they are symptoms of an ordinary spastic or irritable colon. We felt that 22 per cent of the cases we studied showed symptoms which might have been due to inflammation in the pouches. The authors probably referred to the rarity of complications of diverticulosis in the group with simple diverticulosis when first seen at the clinic. Dr Bue does most of the sigmoidoscopic examinations at the Mayo Clinic. He or his collaborators have seen twenty or more of these pouches through the sigmoidoscope. I rather suspect that the third eye which he talked about at the banquet last night must be at the end of his sigmoidoscope. Most of us have not been successful in seeing the pouches. I should like to stress the importance of the differentiation between cancer and diverticulitis. A cancer in the lower six or eight inches of the bowel can almost always be seen. There is rarely sufficient spasm or edema distal to the growth to obscure it. However, in diverticulitis, spasm and edema form such a striking feature that one cannot visualize the actual area of disease. This I think, is an important differential point.

DR JULIUS FRIEDENWALD, Baltimore At one time diverticulosis and diverticulitis were considered rather infrequent but it is now known that they are of quite common occurrence. It is a well established fact that many persons go through life with multiple diverticula without symptoms and that this condition may be detected accidentally, during an x-ray investigation. It is likewise well known that not infrequently evidences of inflammatory changes are noted which give rise to symptoms of a more or less severe type. While many of these cases were formerly treated surgically with a varied degree of success, many according to our experience nowadays yield most satisfactorily to medical measures. Of our acute cases, satisfactory relief was obtained in more than 60 per cent in this manner and but 16 per cent required operative procedures. In the acute stages whenever medical treatment does not afford relief or does not lead to rapid improvement or when exacerbations in the symptoms occur operation should be promptly undertaken. In the more chronic cases with exacerbations and prolonged remissions of symptoms medical treatment alone not only affords prompt relief but may prevent acute exacerbations in the course of the disease. In many instances under our care patients have been maintained in an apparently normal state free from all symptoms, over a period of many years. I am firmly convinced that a great number of persons with diverticulosis pass through their entire life without manifestations of any inflammatory changes whatever and that many others in whom active inflammatory changes occur become symptom free over a period of many years under appropriate medical treatment alone. This consists largely of a diet free of roughage

with large doses of kaolin to be given once or twice weekly, oil retention enemas and liquid petrolatum by mouth.

DR PHILIP WALLING BROWN, Rochester, Minn. In response to the comment of Dr Bockus I wish to urge caution not to be hasty in putting the blame for vague abdominal complaints on colonic diverticula that happen to be encountered during careful study. One sees an occasional patient who has the idea that the diverticula in the colon explain the diarrhea which, of course is not likely. In no wise do I wish to deprecate the possibility that diverticulitis may ensue, but it is odd how few cases were encountered in this study. In more recent years we have observed the same general trend as Dr Friedenwald has that fewer patients need to be operated on. Certainly, the surgeons are glad to be spared these difficult problems.

MORE RECENT DEVELOPMENTS OF HEART FUNCTION TESTS

GUSTAV NYLIN, MD
STOCKHOLM, SWEDEN

The clinical diagnosis of typical cardiac insufficiency with all the signs of congestive phenomena, as a rule, present no difficulties, but with the appearance of these grave manifestations the prognosis is, as a rule, dubious. As within so many fields in modern medicine, an early diagnosis is striven for so that by means of restrictive measures the breaking down of the vital functions of an organ may be delayed as far as is possible or some-

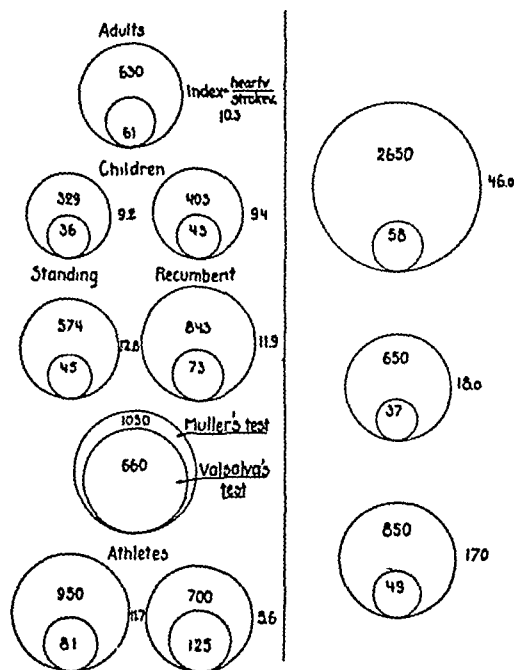

Fig 1—Changes of heart volume and stroke volume during normal conditions and in cases of cardiac decompensation

times even prevented. To arrive at this early diagnosis it is necessary in many cases to make use of functional tests which by increasing the load on the organ aims at elucidating the functions of that organ, in other words a functional diagnosis. There have been abundant opportunities to experience the great importance of this, for example, in the case of the ventricle, kidneys, pancreas and biliary tract. In the case of the heart the great importance of such loading tests has also been realized, but here the appropriate manner of

methodically loading the heart has been difficult to arrive at, and, above all reliable indicators for measuring the work of the heart have been lacking. On the whole, however, there are now three available methods—electrocardiography, roentgenography and physiologic methods for measuring the blood flow, that is to say, the minute volume and the stroke volume of the heart respectively. It was on the basis of these methods that I began my work. I soon found that there was a definite relation between the heart volume and the stroke volume, and I therefore set up an index—heart volume divided by stroke volume.¹ Figure 1 illustrates on one side varying physiologic conditions, on the other, pathologic conditions. The normal material comprises both adults and children. Here are shown the changes between standing and recumbent positions in the same individual. The index, heart volume divided by stroke volume, remains constant. On the other hand, one finds how disproportions appear

for clinical purposes normal values for the heart volume better than by any other method hitherto known, we find that in men of from 20 to 40 years of age the average value of the heart volume is 380 cc per square meter of body surface, with an upper limit of 500 cc per square meter of body surface.

It is a fact that the prognosis in a cardiac case is to a great extent determined by the degree of enlargement, but with less pronounced enlargements it is hazardous to judge the case. At times electrocardiography may show grave alterations in spite of the absence of enlargement; the prognosis is then poor. But in spite of electrocardiography and heart volume determinations in a large number of cases in which perhaps all signs of cardiac insufficiency during rest are absent, one may still be in doubt as to the reserve power of the heart and how the patient reacts to exertion. A function test which illustrates and is calculated to measure this reserve power and to indicate it by a figure

has long been a desideratum. It has been nearly seven years since I began to apply my method at the Serafimer Hospital in Stockholm.⁴ The kind of work has proved to be extremely important. As is shown in figure 3 I have used a specially constructed stairway 1 meter high on which the patients must walk a certain number of rounds at a rate determined by a metronome. The oxygen consumption is first determined during rest and while resting and then exactly between the second and fifth minutes after the cessation of a certain amount of work. The increase in oxygen consumption after the cessation of work is calculated as a percentage of the resting values. In a comprehensive study of normal material, more than 300 persons, this increase has been calculated for three different outputs of work, the lowest being walking on the stairs five rounds at a rate of eighty-eight steps a minute, the second five rounds at

double that rate, 160 steps a minute and the third and the most strenuous work consists of ten rounds at a rate of 208 steps a minute. The highest normal value for the relative oxygen debt, measured according to my method with the different outputs of work, appears to be 30.75 and 112 per cent, respectively.

It is, of course, evident that when walking the same distance a person who weighs 100 Kg. does double the work of one weighing 50 Kg., but the one who is heavier has also a greater oxygen consumption during rest and fasting than the one who weighs considerably less. The consequence is—and this is of immense importance for the value of the test—that the relative oxygen debt, calculated according to this method, is independent of the body weight. This is evident from figure 4, in which no correlation is found between the body weight and the relative oxygen debt with moderate work on the stairs. Nor is this the case with the very strenuous test—ten rounds at 208 steps a minute.

It may now be asked: What is the result of this test in cardiac and pulmonary disease? In a monograph⁵

Fig. 2—Arrangements for synchronized X-ray exposures in frontal and sagittal projections even during work on Krogh's bicycle.

with cardiac decompensation. The heart volume increases and the stroke volume decreases.

On the whole it may be said that stroke volume determinations are of but little practical importance in cardiology while, on the other hand, heart volume determinations are in my opinion of dominating importance. By means of special apparatus, as shown in figure 2, Liljestrand, Lysholm and I have been able even to measure the changes both in heart volume and in stroke volume while work was in progress. By using strong rotating anode tubes and making synchronized exposures in the frontal and sagittal directions we have been able to make volume determinations even while the work was in progress, and we found that with an increasing output of work both the heart volume and the stroke volume increase.

On a comprehensive collection of material of healthy persons Zakrisson and I² have been able to establish

4 Nylin, Gustav. Clinical Tests of the Function of the Heart. Acta Med. Scandinavica, 1933, suppl. 1.

published in 1933 on this function test I have shown that in typical cases of cardiac insufficiency during rest and with symptoms of congestion, for instance enlargement of the liver and edema, the relative oxygen debt

Fig 3—Author's method for working test (The stair is 1 meter high)

in all the cases is higher with the lowest output of work than the highest normal value for healthy persons

I shall now pass on to some cases which illustrate the heart volume determinations and the function tests,

Fig 4—Correlation between the relative oxygen debt and body weight. The abscissa of the upper chart represents the relative oxygen debt at 110 and the abscissa of the lower chart the relative oxygen debt at 100.

set side by side with other observations such as those obtained by electrocardiography, roentgenology and clinical physical examinations

As an example I will describe a case of considerable oxygen debt one attaining a value of 90 per cent, that

is to say, three times the highest normal value for this rate $\frac{1}{88}$, which was of course 30 per cent. The case is one of mitral failure presenting considerable acute enlargement of the liver. Even with these cases of severe insufficiency it may, of course, be of interest to measure the degree of insufficiency, but within this group the function test is of less importance.

On the other hand in cases of latent cardiac insufficiency in which the symptoms of insufficiency are not present during rest and in which all the acute congestive phenomena are conspicuous by their absence, it is of very much greater importance to know how each individual case reacts to exertion. I might mention a

Fig 5—Severe latent cardiac insufficiency in a 26 year old cycle repairer. Mitral and tricuspid insufficiency. The roentgenogram shows enormous dilatation of the heart with a heart volume per square meter of body surface of 1000 cc double the upper limit for normal. The electrocardiogram shows auricular fibrillation extreme right axis deviation coronary insufficiency and positive venous pulse. The function test shows extreme oxygen debt with the moderate test.

case without pronounced congestive phenomena. A man aged 26 with a greatly enlarged heart, more than double the normal size, had mitral and tricuspid insufficiency (fig 5). The electrocardiogram showed auricular fibrillation and extreme right axis deviation. Further the pulse tracing showed a positive venous pulse. The patient, who was up and about, was unable to do more than a slight amount of work but was capable of accomplishing the moderately strenuous test ($\frac{1}{100}$) and then showed an extremely high oxygen debt of 190 per cent as against the normal, which, as will be recalled amounts to a maximum of 75 per cent.

With typical cases of aortic and mitral defects presenting practically normal sized hearts but at the same time without grave electrocardiographic alterations and in which no signs of heart insufficiency are revealed by physical examination, one finds in many instances a normal oxygen debt, even with the most strenuous test

Fig 6—Angina pectoris in a stoker aged 45. The roentgenogram shows a normal size heart. The electrocardiogram is normal when the subject is resting but shows bundle branch block after work. The function test shows considerable oxygen debt with very light work.

For example, a man aged 27 has mitral stenosis with aortic and mitral insufficiency. The configuration of the heart and the heart volume do not diverge considerably from the normal. The electrocardiogram is normal on the whole, and his oxygen debt on the stairs is normal both with the moderate work and with the most strenuous work.

One can also see in this case how repeated determinations with the same output of work give particularly consistent values. It may be said that to a certain extent the size of the heart determines the person's capacity for work, provided there are no coronary alterations. Figure 6 illustrates a case in which the size of the heart was normal in a man, aged 45, whose general condition was excellent and in whom there were no signs of heart insufficiency but whose morbid picture was predominated by precordial pains on exertion and angina pectoris on exertion. The patient during rest

exhibited on the whole a normal electrocardiogram. On the other hand, after light work he showed bundle branch block and a very appreciable oxygen debt of double the normal, namely 61 per cent, with the very lowest output of work which he performed with difficulty. He was up and about the ward and suddenly fell dead three or four days later. The postmortem examination revealed an extreme sclerosis and stenosis in the anterior coronary artery. A similar case is that of a man, aged 41, who had suffered from "angine d'effort" for a year and a half. All clinical signs of cardiac insufficiency were lacking and the heart volume was normal. The electrocardiogram during rest was normal but the work electrocardiogram showed obvious signs of coronary insufficiency, and his relative oxygen debt was obviously pathologic with moderate exertion.

Within the field of pulmonary diseases also this test has its application. In certain cases of severe pulmonary alterations with great restriction of the respiratory parenchyma—for instance in cases of tuberculous pleuritis or pneumothorax—high relative oxygen debts are observed. Figure 7 demonstrates a case of fairly severe silicosis in both lungs as revealed by the roentgenogram of a man, aged 43, with a normal

Fig 7—Silicosis in a old cast metal goods grinder, aged 43. The roentgenogram shows severe silicosis in both lungs. The electrocardiogram is normal. The function test shows severe oxygen debt with mild work.

electrocardiogram but with a relative oxygen debt which even with moderate exertion amounted to double the normal value. In individual cases, especially in young persons, they can get on fairly well even with heavy work with only one lung, as illustrated by a man aged 21, who while doing his military service got spont

taneous pneumothorax which, strangely enough, was not diagnosed until a year later when he, a skilful ski runner, thought that he could not run as well as previously. His function test even with very strenuous work, showed an oxygen debt of only 69 per cent, and this was fully normal.

Jacobæus and I⁵ have experimentally restricted the mobility of the thorax on healthy persons by means of a girdle and have shown that if the vital capacity is decreased by from 40 to 50 per cent the oxygen debt increases correspondingly with heavy work, so that

restricted to about half by means of the girdle, he is able nevertheless to perform the heaviest work on the stairs without any alteration in his relative oxygen debt. I have not been able to attain this result on any other healthy person. In one of my patients, a woman aged 58, the lung ventilation was restricted by a large ovarian cyst, one which contained 25 liters of fluid, and the oxygen debt was more than double the normal, even with slight exertion, but some days later, after the cyst had been tapped, the diaphragm had sunk, as the roentgenogram shows, and she now has, practically speaking, a normal oxygen debt with the same output of work.

The relative oxygen debt is not determined by the heart and lungs only. For instance there is the case of pernicious anemia with a red blood count somewhat over one million in a woman, aged 65, with dilatation of the heart, which receded when the blood values became normal (fig 8). She showed an oxygen debt as high as 131 per cent, that is to say, double the normal with the moderate output of work.

Finally, I would point out the case of pathologic obesity in a man, aged 24, who weighed 142 Kg but who had a normal sized heart, results in the pathologic values of the oxygen debt were 69 and 91 per cent respectively, even with a light and a moderate output of work. Six weeks later, when he lost 24 Kg, the corresponding values were normal (27 and 33 per cent). Twelve weeks later, when he had lost 40 Kg altogether, he was able to perform even the most strenuous test with a normal oxygen debt.

In the cardiac clinic I have received great assistance from the heart function test and the heart volume determination when estimating the reserve power of the heart within various fields of cardiology, especially when it was a matter of deciding whether men were fit for military service, in insurance cases, in advising against certain professions or perhaps to afford indications for provoked abortions.

From what I have said it will be evident that with these three modern methods—determination of the heart volume, electrocardiograms following work and determination of the so-called relative oxygen debt, according to my method—there are greater possibilities of characterizing latent insufficiency of the heart and lungs.

Royal Seraphimer Hospital

Fig 8—Pernicious anemia in a woman aged 65. The roentgenogram shows a considerably enlarged heart when the blood cells are about one million. After treatment and increase of red cells to 4 million the heart volume is normal. The electrocardiogram is normal. The function test shows considerable oxygen debt with mild work when the patient has severe anemia.

even in a healthy person there is cardiopulmonary insufficiency. If this is done with an athlete in very good training for instance Wiklund the Swedish gold medalist in the 30 mile race at the 1936 Garmisch-Partenkirchen he is found to have considerable respiratory reserves. Even during rest he has a vital capacity approaching 7 liters, when this is

⁵ Jacobæus H. C., Nylin Gustaf and Almberg B. Recherches sur l'influence d'une diminution expérimentale de la mobilité du thorax sur la dette d'oxygène après travail graduel. Acta med. Scandinav. 86: 455, 1935.

Bodily Needs and Emotions—In the case of the appetites or desires, the same difficulty is encountered as in dealing with the emotions. The bodily needs represented by hunger and thirst have been attributed, like fear and anger, to sensations arising in the viscera, hunger being due according to this view, to muscular contractions set up in the empty stomach, and thirst to feelings of dryness in the throat and mouth, to which parts the feeling is mainly attributed in consciousness. This view has not been universally accepted and probably only expresses part of the truth for it seems unlikely that needs so fundamental as those for food and drink should not have some direct influence on consciousness in order to ensure their prompt satisfaction. Indeed we see that in those who are addicted to narcotic drugs (morphine, cocaine) deprivation of the accustomed poison soon gives rise directly to painful almost unendurable cravings, and deprivation of such fundamental necessities as food and water may well do the same. Other desires seem to arise at higher cerebral levels. The desire for company for example seems to exist in all animals which are naturally gregarious and represents a social instinct, as does also desire for preeminence or for power over one's fellows while desire for knowledge seems to be allied to the intellectual faculty.—Bosanquet, W. Cecil. *Meditatio Medici*, Gale & Polden Ltd, 1937, p. 109.

PERIRENAL INSUFFLATION

WILLIAM H. MENCHER, M.D.

NEW YORK

With the increase in our knowledge of the syndromes produced by the 'hormonal' tumors, the procedure of insufflation of the perirenal space for purposes of study of both adrenal glands has become a necessary measure in making a general investigation of the endocrine system.

The procedure of perirenal insufflation was introduced by Carelli¹ in 1921 as a means of obtaining better contrast between the kidney and the surrounding tissues. Several others² immediately adopted the procedure for this purpose. However, nothing more was heard of the method until 1935 when Cahill³ reported its value in outlining the adrenals in cases in which these glands were suspected of hypertrophy or of new growth. During the past year I have had occasion to employ the method, slightly modified, in cases in which the adrenal was suspected as the cause of paroxysmal hypertension, of Cushing's syndrome or of masculinism. Several interesting features presented themselves in

Fig. 1—Cross section through lumbar region showing relationship of perirenal (Gerota's) fascia: 1 psoas; 2 sacrolumbalis group; 3 quadratus lumborum; 4 peritoneum; 5 kidney; 6 anterior leaf of perirenal fascia; 7 colon; 8 subperitoneal fascia; 9 posterior leaf of perirenal fascia.

connection with these studies. These points will be noted in the regular perirenal air roentgenograms in the illustrations accompanying this article.

From the surgical service of the Mount Sinai Hospital. The medical and gynecologic services cooperated in the work.

TECHNIC

The patient is placed on the side in the typical position for exposure of the kidney with two or three small sandbags under the loin so as to increase the space between the twelfth rib and the iliac crest. The patient is rotated somewhat forward so as to allow the peritoneal contents to fall away as much as possible from the

Fig. 2—Case of virilism. Insufflation of right perirenal space shown; no lesion. Other side also normal. Ovaries showed thecal cell hypertrophy.

site of injection. The twelfth rib and the outer edge of the erector spinae muscles are outlined with tincture of mercurochrome. An acute angle is thus formed by the junction of these two lines. The skin is then prepared with tincture of iodine as the skin disinfectant as for any operative procedure. The mercurochrome lines will stand out prominently under the iodine coating. A small amount of procaine hydrochloride is injected at the angle. An ordinary spinal tap needle is introduced in a direction pointing slightly upward toward the twelfth rib and somewhat forward and away from the erector spinae muscles. The needle is introduced until Gerota's fascia has been pierced. A definite sensation of perforation of this membrane is usually experienced. Aspiration at this level is made so as to be sure that the needle does not lie in a vessel. The needle is then attached to the air delivery system which consists of a two-bottle (calibrated) pneumothorax outfit and two glass attachments for washing and filtering air. Air is delivered doubly filtered through cotton and washed by 1:500 mercury bichloride solution under 6 inches of gravity pressure. If the proper plane has been entered the air will bubble freely under this small amount of head pressure. At the outset I employed from 200 to 300 cc. of air but found this amount usually insufficient for adequate x-ray contrast. Lately I have increased the volume as needed up to 550 cc. and have produced pictures with better visualization. The needle is removed after the introduction of the air and the puncture site is coated with collodion. The patient is then asked to sit up and perform rowing exercises for

about ten minutes. This measure places the air about the kidney and under the diaphragm. When flexion exercises are not feasible, manual massage over the kidney may be employed with similar results. X-ray films are then taken in the antero-posterior and in the oblique position. The plate taken in the oblique position has usually given the better visualization. Roentgenograms taken in the lateral position are of the least benefit, since the spine interferes in this plane. The two plates have usually been sufficient for diagnostic purposes. No further roentgenograms have been found necessary at later periods as recommended by Cahill. In several instances I have employed intravenous or retrograde pyelography during the time the air remained about the kidney.

In my hands the method has been devoid of any untoward effects. In some instances there is complaint of fulness in the loins. In several cases after sitting up

air outline in three of my last five cases, in which I increased the gravity pressure (fig 8). The pericardium is seen separated from the mediastinal pleura

Fig 3.—Hirsutism in a girl aged 16 years. Insufflation of the right perirenal space showed no lesion. Note air just beginning to fill left perirenal space from the insufflation on the right side.

the patient has complained of a little pain in the shoulder corresponding to the injected side. This is indicative of the presence of air extraperitoneally under the diaphragm. In one of my early cases mediastinal emphysema was noted several days later when a routine roentgenogram of the chest was taken. The patient had no subjective complaints. On examination some emphysema was palpated in the neck. This phenomenon was described by Chevassu and Maingot⁴ who used larger amounts of gas. In their case mediastinal and cervical emphysema occurred during the injection and the patient complained of a sense of suffocation. The perirenal insufflation was unsuccessful. It is quite possible that in their case, the gas was introduced directly into the mediastinum.

Since my first case of emphysema was noted I have taken immediate and late roentgenograms of the chest as a routine and have obtained a positive mediastinal

Fig 4.—Case of hirsutism showing hump on convex border of left kidney.

Fig 5.—Oblique view in a case of severe paroxysmal hypertension. Large adrenal tumor (pheochromocytoma). Note well defined perirenal fascial envelope (Gerota's fascia).

In one film a definite outline of the aorta is seen from the arch down to the area of the kidney. It is my idea that the pathway of air to the mediastinum is by way of the renal pedicle and thence along the aorta through

the aortic opening in the diaphragm. This was partly borne out by a study of one of my x-ray plates in which the aorta is seen outlined from the region of the renal

Fig 6—Oblique view in a case of Cushing's syndrome. Small tumor of adrenal (adenoma)

Fig 7—Oblique view in a case of Cushing's syndrome. Large adrenal tumor (adenocarcinoma)

pedicle to just above the diaphragm. In one case in which one side was insufflated, air could be seen beginning to surround the kidney on the other side (fig 3). Finally, a study of the anatomic relationships of the

perirenal or Gerota's fascia (fig 1) favors the foregoing conclusions as to the possible pathways of air. Briefly, the perirenal fascia envelops the kidney and adrenal, fusing above with the tissues in the diaphragmatic region and below with the subperitoneal tissue in the iliac fossa. Mesially, the anterior leaf of the fascia runs over the vertebral column and prevertebral vessels to join with the perirenal fascia of the opposite side. The posterior leaf fuses with the subperitoneal tissue near the spinal column. None of my cases of mediastinal emphysema had any untoward symptom. To obtain mediastinal films it is advisable to raise the gravity pressure from 18 to 24 inches after equilibrium has been established at the 6 to 8 inch gravity level.

A method is thus suggested for outlining mediastinal lesions, especially tumors, by an extrathoracic procedure that is practically devoid of danger. The method of injecting air directly into the mediastinum by the paravertebral route and through an area in which important structures are present is theoretically more hazardous. I propose to employ the perirenal method for visualization of mediastinal lesions and shall report on this phase at some future date.

Fig 8—Mediastinum outlined after perirenal insufflation

Distinct delineation of both leaves of the diaphragm is also noted, especially in the films taken in the lateral position. Thus an extraperitoneal method is also suggested for investigating the subdiaphragmatic regions for suspected lesions by the insufflation of air. To date I have performed perirenal insufflations some twenty-two times in ten cases. In all except one case the procedure was performed in one or two sittings. In three instances the films were positive (figs 5, 6 and 7) for adrenal lesions. Operation was done in all three cases. In one (fig 5), a case of severe paroxysmal hypertension, the tumor proved to be a large pheochromocytoma.

In the second case, in which the symptoms were typical of so-called Cushing's syndrome, the tumor was an adenoma (fig 6). It was evident in this case that the diagnosis could not have been made without visualization of the perirenal space, since other types of x-ray study gave no indication of a tumor in the adrenal area.

In the third, also a case of Cushing's syndrome, the tumor was an adenocarcinoma (fig 7). (The latter two cases are to be reported by B. S. Oppenheimer and Solomon Silver.)

One case of masculinism with hirsutism proved to be negative as far as the adrenals were concerned and exploration was performed by Dr R T Frank for arrhenoblastoma of the ovary Both ovaries showed microscopically "a perifollicular and diffuse hyperplasia of the theca interna cells"

In another case of hirsutism and urinary incontinence a "bump" was seen on the convex surface of the left kidney (fig 4) In this case exploration of the left kidney will be done and of the ovaries if the former is found to be normal

The other cases showed no definite lesion in the adrenal area There is little difference except in absorption time between air, oxygen and carbon dioxide as the means of gaseous contrasts The three have been used with equally good results Carbon dioxide is absorbed most quickly, while air remains for some time (up to two weeks in one case)

PARTIAL GASTRECTOMY FOR GASTRIC OR DUODENAL ULCER

SAMUEL F MARSHALL M D
AND
EVERETT D KIEFER, M D
BOSTON

Subtotal gastrectomy has become a well recognized and established procedure in the surgical management of gastric and duodenal ulcer That it has become a controversial subject cannot be denied There are, on the one hand, surgeons who are highly enthusiastic for the more radical methods and on the other, those who advocate more palliative operative procedures We believe that somewhere between these two points of view, at least today, rests a satisfactory position but that partial or subtotal gastrectomy is the method of choice when limited to properly selected cases It naturally

Fig 1—The common locations of gastrojejunal and jejunal ulcers following gastroenterostomy

follows and should be emphasized that it is impossible for one method to fit every patient or every type of ulcer We therefore present from the experience of the Lahey Clinic what we consider the indications for partial gastrectomy, the surgical and gastroenterologic aspects of the operation and the end results in 102 cases in which the procedure was performed for gastric or duodenal ulcer We shall also discuss briefly the surgical technic employed and the type of anesthesia we have found most useful

Two hundred and forty-two patients were operated on for gastric, duodenal or gastrojejunal ulcer in the Lahey Clinic in the ten years from Jan 1, 1927, to Dec 31 1936 This number does not include patients

with acute perforation The type of ulcer and the method of treatment for the 242 patients is shown in the accompanying table

Certain clinical features have proved to be definite indications for surgical intervention in the management of patients with duodenal ulcer It is obvious that acute perforation requires immediate surgical intervention, and this fact needs no comment Patients with intractable ulcer, who for one reason or another fail to obtain relief with adequate medical care, are forced to submit to operation for control of their disease Pyloric obstruction occurring with symptoms of active ulcer is commonly due to spasm, infection or edema, and in most instances can be relieved by rest, diet and alkalization However, recurring bouts of acute ulcer produce narrowing of the pylorus shortening of the duodenum by scar formation and real cicatricial stenosis, which necessitates surgery From a statistical study by one of us¹ of a large series of cases of duodenal ulcer, gross hemorrhage was found to indicate a somewhat more severe type of ulcer and its presence to decrease the probability of successful medical management Recurrence of gross hemorrhage in spite of adherence to a regimen for ulcer is a definite indication for surgical intervention, since the prognosis with continued medical management is poor Since gross hemorrhage is a serious complication in patients with ulcer, carrying with it a definite mortality rate of at least 5 per cent, we have established the policy of advising surgical treatment for patients with serious recurrent hemorrhage

The indications for surgical intervention in cases of gastric ulcer are somewhat different because of the different clinical features of gastric lesions in contrast to duodenal ulcer and particularly because of the diagnostic difficulty in distinguishing between some gastric

ulcers and early carcinoma It has been definitely established and reported by Dr Sara M Jordan of this clinic that a large percentage of gastric ulcers will heal readily and completely with medical treatment Surgical treatment is therefore indicated only for the gastric ulcer which because of the large size of the

crater or extension into adjacent tissue proves intractable with medical measures and for the ulcer which because of insufficient tendency to heal during medical management is suspected of being an early carcinoma. Recurrent massive hemorrhage is an indication for operation although it occurs less frequently from gastric ulcer than from duodenal ulcer, in 11 per cent as opposed to 18 per cent of cases. Obstruction is rarely

Fig 3—A man aged 26 had a history of recurrent attacks of ulcer for six years. A roentgenogram (left) of the stomach taken before operation showed hypertrophied gastric rugae, active peristalsis and a markedly deformed duodenum. A gastric analysis after an Ewald meal showed a free acid of 40 and a total acid content of 6. A roentgenogram (right) taken fourteen days after operation showed a gastric stump about one-fifth the size of the stomach with a good functioning stoma and no dilatation of the jejunum. The gastric analysis after injection of histamine showed no free acid and a total acid of 34. The convalescence was smooth and the final results were excellent.

an indication for operation in cases of benign lesions. Dr. Jordan has repeatedly shown that the most practical method of differentiation between benign and malignant gastric lesions is to employ a period of medical treatment for ulcer with repeated x-ray examinations of the stomach.

The preoperative decision pertaining to the nature of a gastric lesion is often of more value than the decision made at time of surgical exploration. As has been frequently declared by Dr. Lahey, it is often impossible at the operating table to tell whether the lesion is benign or malignant. Consequently a radical removal must be done unless preoperative data have determined the nature of the ulcer.

The selection of the type of surgical procedure is complicated by many factors and no surgeon experienced in gastric surgery will claim that partial gastrectomy should be performed in every case of ulcer. Unquestionably the less radical and more palliative types of operation must be utilized in many instances to avoid a prohibitive mortality rate. Pyloroplasty with excision of the duodenal ulcer has a limited application to the severe type of ulcer ordinarily referred to our surgical section for operation. It is not consistently applicable to large eroding ulcers of the posterior wall when the duodenum cannot be mobilized.

Gastro-enterostomy in properly selected cases promises great benefit, because of its low mortality rate and the smooth convalescence. It is our firm conviction, however, that gastro-enterostomy should be restricted to patients who are past middle age who have low acids and who have considerable cicatricial pyloric obstruction. Unquestionably the best results are obtained in this type of case. Not infrequently because of the poor

physical condition of the patient one must employ gastro-enterostomy, although recognizing at the same time that it is not the most satisfactory method for that particular lesion.

The most serious complication following gastro-enterostomy is the development of gastrojejunal or jejunal ulcer. It occurs after any operative procedure for ulcer in which the stomach is anastomosed to the jejunum and is not peculiar to gastro-enterostomy. However, it is more commonly seen after gastro-enterostomies, particularly in young persons with high gastric acids. Lahey and Swinton³ in reviewing the literature on this subject found that the reported occurrence of gastrojejunal ulcer following gastro-enterostomy ranged between 17 and 24 per cent and it is our opinion that the incidence is nearer 24 per cent than 17 per cent. Postoperative jejunal ulcer can also occur after partial gastric resection but does so with much less frequency than after gastro-enterostomy. In our series of 102 patients seventy-four of whom were followed postoperatively five or 67 per cent had postoperative ulcer. Practically all gastrojejunal ulcers are jejunal in location (fig. 1), and they may be at the very margin or at varying distances from the stoma. Jejunal ulcer is accompanied by severe symptoms usually far exceeding in intensity the distress due to duodenal ulcer and are characterized by an increased tendency to bleed by intractability to medical management and by a tendency to perforate into the abdominal cavity or into the colon thus producing a gastrojejunal colic fistula. Surgical intervention is required in a large majority of the cases and carries with it a mortality rate from four to five times that of the primary operation.

The greatest benefit accomplished by the surgical management of ulcers results from the change in the gastric secretory and motor function and there is little doubt that, of all operative procedures, partial gastrectomy best accomplishes this change. The decrease of the gastric acidity with this operation is due (1) to rapid emptying, with a decrease of the gastric secretory phase (2) to a reduction of the secretory mucosa and

Fig 4—A the Hoffmeister type of gastrojejunal anastomosis following subtotal gastrectomy. B a modification of the Hoffmeister anastomosis reinforcing the closed end of the stomach with jejunum. This is considered the procedure of choice.

(3) to neutralization of gastric acidity by the regurgitated alkaline duodenal contents.

Partial gastrectomy is an operation of considerable magnitude beset with many technical difficulties and may be accompanied by a considerable mortality even in the hands of the most experienced and skillful sur-

geons. In our earlier cases the mortality of this operation ran prohibitively high with a rate of 18 per cent but with an increasing experience in the technical details and with a better selection of cases the mortality should certainly not be much greater than that associated with gastro-enterostomy. During the past year there have been four deaths in thirty-four cases which is a mortality of 11 per cent. This rate is undeniably high but it is frequently unfair to compare the mortality rates of two series of cases on a strictly percentage basis. Two prominent groups of factors influence the death rate for subtotal gastrectomy: first the technical factors relating to the operation and the anesthesia and second the group of factors pertaining to the general physical condition of the patient and to the pathologic picture of the ulcer including its size, depth, location and chronicity and the involvement of surrounding tissues. Ulcers situated on the anterior wall of the duodenum or near the pylorus present few technical difficulties and are comparatively easy to remove and with them the mortality should not be higher than that associated with gastro-enterostomy.

In this clinic the management of ulcer has always been placed in the hands of the gastro-enterologic division, and the policy has been a conservative one. Surgical treatment has been reserved for the patients whose ulcer has not been controlled by what we consider adequate medical management, consequently no patients with mild uncomplicated ulcers have been operated on. We do not consider medical treatment to be adequate unless the patient has had at least three weeks of hospital treatment followed by a carefully supervised maintenance regimen for an indefinite period. A recurrence of symptoms caused by careless dietary or living habits and the mere wish to avoid the so-called ulcer life have seldom been considered indications for surgical treatment.

In the last ten years of 1,930 patients with duodenal ulcer only 157, or approximately 8 per cent, have been operated on and of 192 patients with gastric ulcer only forty-four have been surgically treated. It has been our experience that ulcers which have been uncontrolled by adequate medical management are particularly severe ulcers, that is large eroding penetrating lesions of the posterior wall involving the pancreas often associated with a duodenum buried in periduodenal adhesions indurated and adherent to the liver gallbladder and common duct, or ulcers with serious associated complications such as chronic obstruction or recurrent hemorrhages. It is this type of ulcer frequently occurring in a patient with some constitutional or physical disability that our surgical staff is called on to treat. Obviously, unless operation is refused in some of these cases the surgical division comes to be filled with patients who are technically difficult to treat or poor risks.

Severe ulcer was present in sixty-six patients, or 65 per cent, of the series of 102 patients operated on and studied postoperatively. A few of the ulcers were so adherent to the pancreas and to the common duct that removal would have been accompanied by a mortality so high that the surgeon had no justification for persisting in their excision. In eighteen cases such a con-

dition existed and the division of the duodenum was made just beyond the pylorus or just proximal to it the ulcer being left in situ, after the manner proposed by Finsterer (fig 2). A high resection was then carried out in the usual manner. The ulcer which is permitted to remain is thus sidetracked from food and acid gastric juice and is bathed constantly in alkaline duodenal contents. We do not believe however that this method should be used in the presence of high grade pyloric obstruction because of the danger that accumulating secretions above the stenosis will cause the suture line of the inverted pyloric stump to give way. This serious complication occurred in one of our cases and death resulted from peritonitis.

It is important to emphasize that the purpose of any operation designed to treat peptic ulcer is to relieve the symptoms, to prevent serious complications and to guard against any recurrence. Subtotal resection more nearly meets these requirements than any other proce-

Fig 5.—The stomach is mobilized and the duodenum divided. a line of resection of the stomach. b method of closure of the duodenal stump.

cedure, and we believe that if through widened experience one can reduce the operative hazard it will prove to be the best method now available.

The importance of preoperative management and postoperative care rivals that of the surgical procedure itself. We have not space in this paper to devote to a discussion of the details of this subject but persons who are interested may refer to a discussion of the problem recently published by one of us.⁴

The technical difficulties of such a formidable operation as partial gastrectomy are considerable and are to be surmounted only by an extensive experience with gastric surgery. Once having decided on a radical attack on the ulcer one should really carry out a radical removal of the stomach. While pylorectomies and antrumectomies have a mortality rate as high as partial resection they have little advantage over a gastro-enterostomy because they fail to remove a sufficient amount of the stomach and consequently fail to decrease gastric acidity. Partial gastrectomy involves removal of at least three fourths or four fifths of the stomach.

The operation should be radical enough to produce anacidity or hypo-acidity, and a recurrence of symptoms may follow the failure to obtain this result (fig 3)

Provided resection of the stomach has been sufficiently radical, we believe that it makes little difference what type of anastomosis is made. The Billroth I type of procedure frequently cannot be used with the large adherent, eroding ulcers, which do not permit sufficient mobilization of the duodenum to make possible anastomosis of the duodenum without tension to a radically resected stomach. Many modifications of the Billroth II method can be utilized safely and satisfactorily. We have gradually come to employ a modification of the technic as proposed by Hoffmeister and have found it most satisfactory (fig 4)

The actual removal of the major portion of the stomach does not present any particularly trying technical difficulties, but painstaking precautions must be

Fig 6—The stomach is divided by cautery between the double row of clips applied by the de Petz clamp. Inset shows the application of the de Petz sewing clamp

taken against contamination by spilling of the gastric contents and against hemorrhage. The real technical problem comes with the removal of large gastric ulcers which are penetrating and adherent to the pancreas and particularly with the removal of deep eroding adherent ulcers of the duodenum. The incision in the abdominal wall is made preferably to the left of the midline and of sufficient length to permit adequate exposure. Since the pylorus is normally only slightly to the right of the median line, it is easily approached by a left rectus incision, which allows a better approach to the body and lesser curvature of the stomach. Dr. Lahey has proposed and for a long time we have used a waterproof abdominal pad, consisting of gauze with cellophane stitched between the layers, to protect the edges of the wound and to wall off the rest of the abdominal cavity from contamination. Mobilization of the stomach is begun by division of the gastrocolic and the gastrohepatic omentum. One must exercise care to avoid injury to the middle colic artery which lies immediately adjacent and just posterior to the pyloric

area of the stomach. The pylorus and the ulcers of duodenum having been freed, the division is made through the duodenum just distal to or even through the ulcer. Great caution must be used to prevent injury to the common duct or to the pancreas and to leave enough of the duodenal tube to permit easy inversion and safe suture. We emphasize the importance of saving every possible bit of the duodenal tube and not wasting any of it by suturing over a clamp. This may be accomplished by opening the duodenum widely and by closing it with an in and out Connell suture of catgut or by grasping the divided duodenum with Allis clamps and closing with a continuous suture of catgut followed by inversion (fig 5). The closing is reinforced by a second catgut suture layer and finally reinforced with interrupted silk sutures. The divided ends of the omentum are then sutured to the duodenal stump for reinforcement. Frequently, when the duodenal stump is shortened and difficulty is encountered in obtaining a safe closure, it may be buttressed by suturing it against the head of the pancreas. The mobilization of the stomach is then completed by turning the stomach to the left and by dividing the left gastric artery, which is doubly ligated. The gastrocolic and the gastrohepatic portions of the omentum are further divided on each border about 4 or 5 cm above the point at which the stomach is to be cut across (fig 5).

We have found the de Petz sewing clamp, or the Fredericks modification of it, to be of great value, and we have employed it in practically all our resections. It prevents soiling, facilitates the closure, saves time, controls hemorrhage and undoubtedly reduces the technical difficulties. The resection is completed by cauterizing division between the double row of clips, which have been inserted by the de Petz clamp (fig 6). The upper portion of the resected end of the stomach is then inverted with a double row of catgut sutures and reinforced with interrupted silk sutures, a sufficient opening being left at the lower end of the closed stomach for the anastomosis. The jejunum is then brought anterior to the colon, a good sized loop (from 12 to 16 inches, or 33 to 40 cm) being allowed to remain between the Treitz ligament and the stomach, and the anastomosis to the cut end of the stomach is begun. It makes little difference whether the proximal jejunal loop is placed at the greater curvature or at the lesser curvature of the stomach. We have had good results with each method. A posterior row of interrupted silk sutures is used to unite the jejunum to the divided end of the stomach, the jejunum is then incised, and the stomach is opened by cutting away the remaining clips, all bleeding points being ligated. The posterior row is then completed with a second continuous interlocking catgut suture, this catgut suture is continued on to the anterior row as a Connell in and out suture, thus inverting all the mucosa and completing the closure of the stomach. The anterior row is further reinforced with interrupted silk sutures. The jejunum is further buttressed by silk sutures against the upper closed end of the stomach (fig 7). Particular attention is paid to the angle which are reinforced with silk sutures and by suturing the divided gastrocolic and gastrohepatic omentum onto them. With completion of the resection the abdominal cavity is inspected for bleeding points and then closed without drainage. The abdominal wound may be closed by layer sutures of catgut or by means of through and

through sutures of heavy black silk, after the peritoneum is closed with catgut. This method greatly decreases the time of closure and best prevents disruption of the wound. Immediately after the operation we regularly employ a blood transfusion and believe it is of great value, since many of the patients are of necessity in poor general condition.

The choice of a satisfactory anesthetic is of the utmost importance in gastric surgery. The technical difficulties are made immeasurably easier with complete relaxation, which permits adequate exposure without the added trauma of constant forceful retraction. Spinal anesthesia produces the most satisfactory relaxation and exposure. Of the drugs available for spinal anesthesia, nupercaine in a dilute solution as proposed by Mr. Howard Jones, with a method as modified by Dr. P. D. Woodbridge of our anesthesia department, offers the greatest possibility for prolonged anesthesia without the undesirable drop in blood pressure. Nupercaine in a 1:1500 dilution has proved so satisfactory when anesthesia of especially long duration is required that we employ it to the exclusion of all other anesthetics. Excellent relaxation is obtained by this method over periods extending up to three and four hours if necessary. Previous to the development of dilute nupercaine solution we employed intratracheal administration of cyclopropane combined with wide infiltration of the abdominal wall with 0.5 per cent procaine solution. In addition, splanchnic anesthesia was used to increase the degree of relaxation and to prevent the fall in blood pressure which so often results from traction on the stomach. We have not found splanchnic anesthesia to be necessary when spinal anesthesia with nupercaine is employed. The expert advice of a well organized anesthesia division is a most desirable feature in any type of abdominal surgery, but we know of no operative procedure in which the application of this special knowledge is of more value than in major gastric operations.

The most disturbing complications were those of a pulmonary character such as pneumonia, pulmonary edema and atelectasis, which accounted for 50 per cent of all fatalities. Hemorrhage rarely occurred. Failure to control all bleeding points at the time of operation is responsible for most cases, although sloughing of the suture line may occasionally cause hemorrhage, and twice we have seen fatalities result from this. We must admit from experience that the so-called hemostatic stitch put in the cut stomach wall does not protect all patients from postoperative bleeding, and we have for some time practiced ligation of all vessels in the divided end of the stomach.

Intra-abdominal infection accounts for a small percentage of deaths, but we believe that if soiling from spilled gastric contents were eliminated, peritonitis would be an infrequent cause of postoperative mortality. One death was due to perforation of the stoma due to the giving way of the suture line, but with the employment of silk suture material in the outer layers, this should not occur.

Intestinal obstruction following partial gastrectomy is usually caused by edema in the mesocolon and most

commonly occurs in the distal loop beyond the point of anastomosis. When gastric stasis persists beyond eight or nine days, edema is usually not the cause and the failure to drain is usually due to obstruction in the jejunum; reoperation then must frequently be carried out.

During the past two years we have employed an antecolic anastomosis, bringing a long loop up over the transverse colon and anastomosing it to the cut end of the stomach, and no postoperative obstruction has resulted, no entero-enterostomies between these loops have been done. The use of the Levine tube in all cases postoperatively, passed through the nose or the mouth, permits free drainage of any gastric or duodenal contents until normal peristalsis and drainage are resumed.

In general the period of convalescence after partial gastrectomy is extended. A few patients return to work within a period corresponding to the period of disability following cholecystectomy, but the frequent

Fig. 7—Hoffmeister method of gastrojejunostomy, the upper half of the divided end of the stomach is closed inverting the clips. The jejunum is sutured to the remaining portion of the stomach. The clips are cut away in this area and the jejunum is incised forming the stoma; the anastomosis is then completed.

and more common experience is for the patient to remain unable to work for from three to six months after leaving the hospital. Not a few are disabled for as long as a year or more. The disability is usually characterized by general weakness, failure to regain normal weight, neurasthenia and some distress following ingestion of food.

The final clinical results are quite satisfactory and compare favorably with the end results of any major surgical procedure. Of the series of 102 patients on whom gastric resection was done, seventy-four were accurately followed and the results in 84 per cent can be classified as good or excellent. The patients are well, almost as robust as ever and live under few dietary restrictions. In 9 per cent the results were recorded as fair or poor. These patients have symptoms which are apparently caused largely by functional disorders of the gastro-intestinal tract or by neurasthenia.

Five patients, or 67 per cent, had postoperative ulcer, three have recovered with surgical help and are now well. One is still an invalid and the fifth has not

returned to us although it is reported that he has had three hemorrhages. It is the general experience that postoperative ulcer is associated with persistently high gastric acidity. This was true in all five of our cases. Of the eighteen patients in whom high resections were done and the duodenal ulcer allowed to remain in situ after the manner of Finsterer, fifteen have been accurately followed and fourteen have exhibited no evidence of recurrence of symptoms and are apparently in good health. One had a jejunal ulcer eleven months after operation and was treated medically, with relief of all symptoms.

The postoperative gastric acidity was studied in fifty-five patients, thirty-five, or 64 per cent, showed either achlorhydria or hypochlorhydria (a free acid less than 10) after an Ewald test meal. Twenty patients, or 31 per cent, showed free acidities of over 10, the highest acid was 52, occurring in one of the patients with postoperative ulcer. However persisting acidity does not necessarily indicate a poor clinical result, since the results in eleven of the twenty patients with a moderately high acid content were classified as excellent. It is not exactly clear why as high a percentage of achlorhydria should be produced by this operation, since much of the acid-producing mucosa is not resected. The removal of the antrum eliminates only the gastric phase of secretion and does not affect the continuous type of secretion which is apt to be high with ulcer. If the so-called continuous phase is not too active regurgitation of jejunal contents completely neutralizes the acid produced, otherwise highly acid gastric juice may enter the jejunum, so that it would seem that unless anacidity or hypo-acidity is produced by a sufficiently high resection the operation has but little clinical advantage over gastro-enterostomy.

An anastomosis which permits free regurgitation also permits rapid emptying of the stomach. It is common for patients to complain of a decreased capacity for food characterized by some sense of fullness and distress immediately after eating. This symptom ultimately disappears in most cases. There is x-ray evidence of some jejunal dilatation in many cases; this is marked in only a few. In conjunction with the decreased capacity for food many patients experience difficulty in regaining normal weight. This is an important factor in the long period of postoperative disability present in some cases. It is a common observation that the resected stomach evacuates a barium meal in much less than normal time and the intestinal absorption is undoubtedly impaired. Diarrhea is not uncommon but usually subsides within a few weeks after operation.

SUMMARY

According to our experience at the Lahey Clinic in the surgical management of duodenal and gastric ulcer, but a small percentage of patients with ulcer require surgical management.

Experienced surgeons have a wide range of opinion regarding the employment of partial gastrectomy for peptic ulcer and we believe that no one operation is applicable to all patients with ulcer. We agree with Dr. Lahey in his statement that gastro-enterostomy should not be employed as a matter of routine for duodenal ulcer, jejunal ulcer with its high operative mortality may occur following such a procedure.

Certain disturbing facts must be admitted regarding partial gastrectomy, first the operative risk which the

patient must face, second, the economic factor or period of disability, third, the changes and adjustment in gastric physiology, and fourth, the final gains in the control of the patient's disease. In any case in which the question of surgical treatment arises, it is necessary to balance these factors against risks and expectations offered by medical measures.

Postoperative mortality is plainly influenced by the choice of case as well as by technical points in the surgical procedure and the anesthesia employed. With deep eroding ulcers of the posterior duodenal wall making up the majority of cases treated by surgical procedure, the mortality will be high with radical methods but the operation unavoidable.

It is important to strive for postoperative anacidity because of the occurrence of jejunal ulcer in patient in whom the acid has not been sufficiently reduced by partial resection. Unless anacidity or hypo-acidity is produced by high resection, it is difficult to see any clinical advantage of this operation over gastro-enterostomy.

605 Commonwealth Avenue

ABSTRACT OF DISCUSSION

DR. EVERETT D. KIEFER, Boston. As stated in the paper the ultimate results are satisfactory in a large proportion of cases and it is true that the operation is often in the nature of a providential delivery from an impossible situation. It is only necessary, therefore, to point out that it is not all sunshine after a successful subtotal gastrectomy. The period of postoperative disability tends to be an extended one. In not a few cases it is from six months to a year before the patient is able to resume his work. Difficulty in regaining normal weight and vigor is often present. Apparently, the situation is related to insufficient food intake due to quick satiation of the appetite at mealtime. Certain readjustment in the mechanics of the digestive tract such as the rapid emptying of the stomach and distention of the jejunum, produce sensations that may be disturbing to the patient. The most distressing incident that may occur is the formation of a jejunal ulcer. Present reports indicate that this complication arises in about 6 per cent of cases and as time goes on the percentage is more likely to increase than decrease. There are some cases in which a highly acid gastric juice continues to be produced even though the resection is a high one. Postoperative film of two cases in my possession indicate a reasonably high resection yet gastric hyperacidity was not controlled and ulceration of the jejunum resulted. Therefore, one must conclude that although the use of subtotal gastrectomy constitutes a major advance in the surgical treatment of ulcer there is a small group of patients for whom this operation is not the final answer to their disease.

DR. RICHARD LEWISOHN, New York. I agree with Dr. Marshall and Dr. Kiefer that partial gastrectomy is not applicable to every case. I have always claimed that the mortality would go up very high if one would not select the cases properly. In my series I have excluded about 12 per cent from gastrectomy. In order to get a safe closure in the Finsterer operation the pylorus and part of the antrum must be left. Thus it follows these cases over a long period of years one may observe a fairly high percentage of gastrojejunal ulcers. In the acute perforations many surgeons in Europe do primary partial gastrectomy. In this country we do not believe in that procedure. We simply close the perforation. However I do not feel that a great many of them are really cured. In my series 40 per cent have persistent symptoms of ulcer following the closure of an acute perforation and require secondary gastrectomy. The general condition of the patient is of the greatest importance in selecting the operative procedure. I do not agree with the authors as to the long convalescence following partial gastrectomy.

trectomy In my experience at Mount Sinai Hospital, which extends over fifteen years, we have not had that experience. In fact we have been impressed by the very smooth convalescence immediately after the operation and after the patients leave the hospital. Our statistics on gastroduodenal ulcers following partial gastrectomy were published recently. We have not cured all our patients and we have not prevented recurrences, but we have reduced them from 34 to 67 per cent. If one selects the cases gastrectomy is not a formidable operation. My mortality in primary chronic cases, of gastroduodenal ulcers not including secondary cases not including the cases of acute hemorrhage, in which the mortality has been high, not including secondary operations for gastroduodenal ulcers, in which the mortality is also high is 3 per cent and that is as low as we can get it. I do not think that the last word has been spoken on the treatment of ulcer. Undoubtedly gastrectomy for ulcers is a major operation. The ultimate cure must come from the medical men, who will show us how to treat these cases properly medically and cure them permanently without surgical intervention.

DR FRANK LAHEY Boston I want to say a word based on my experience with these cases. I think it is of interest to state how my associates and I determine what type of operations we do. The most important thing particularly with duodenal ulcers is the demonstration of the relation of the location of the ulcer to the point where the common duct enters the duodenum as the authors have stated. That is the first thing we do, we find where the common duct enters the duodenum and how close the ulcer is to it. There is nothing more distressing than to remove these ulcers well down on the posterior wall of the duodenum close to the papilla and then find that one does not have enough duodenum to close the opened duodenum safely. First establish the relation of the common duct to the ulcer. Next establish the patency of the pylorus. If the ulcer is too close to the entrance of the common duct the ulcer should be left behind as suggested by Finsterer, the duodenum cut off next to the pylorus and its end turned in and a high subtotal gastrectomy should be done on the remaining stomach. It is even worth while in many cases to cut the stomach off proximal to the pylorus, leaving the entire duodenum with its contained low and duodenal ulcer together with the pylorus. It is of great importance in such cases to be sure that the pylorus is patent. If the pylorus is not patent, the only operative procedure possible is a gastroenterostomy. I once left a duodenal ulcer in place cut the stomach off just proximal to the pylorus and turned it in when the pylorus was not adequately patent. This resulted in a blow out of the turned in stomach owing to the accumulated secretion, which did not drain into the pylorus. The two very important decisions to make in the selection of the type of operation to be employed, particularly in duodenal ulcer are the relation of the ulcer to the common duct and the patency of the pylorus. I agree that the last word has as yet not been said regarding either the medical or the surgical treatment of peptic ulcer.

DR SAMUEL F MARSHALL Boston Dr Kiefer rightly cautions us against overenthusiasm for this method, and it must be applied to cases selected with a great deal of care. The cases which we have selected and to which we have applied this operation, have been severe cases and we believe that the operation has been unavoidable. Dr Lewishohn has pointed out the mortality rate. We agree that it is high but we have included the fatalities that have resulted following subtotal resection for gastroduodenal ulcers and also following operations for gastroduodenal fistula. Dr Lahey has brought to our attention the problem of pyloric obstruction where we are doing these Finsterer procedures. I do believe however that Dr Kiefer was not talking about the immediate postoperative results because these patients have a smooth convalescence. The majority of patients have a convalescence immediately after operation that is comparable to that following appendix operations. It is really amazing how well they get along but we must emphasize that it is perfectly true that the late convalescence is not always the most desirable.

PULMONARY EMBOLISM

ARLIE R BARNES MD

ROCHESTER MINN

An operation in which the patient has weathered all other hazards, a fracture that is healing satisfactorily, a puerperium in which all appears to go well, a thrombophlebitis in which the patient is well on the way to recovery or a minor sprain or bruise may be the setting for death from pulmonary embolism. The great tragedy of such a death is that in almost every such case the accident of pulmonary embolism was the sole barrier that stood between the patient and recovery. Its sudden and unpredictable occurrence comes as a terrible shock to the relatives of the patient and his physician and robs the physician of a well earned and successful result. And for every fatal attack there

Fig. 1—Fatal pulmonary embolism. A massive thrombus is coiled in the right ventricle and extends into a main division of the pulmonary artery. Minor pulmonary embolism often precedes this fatal attack.

occur two or three instances of nonfatal seizures attended by grave apprehension for the patient's life, meanwhile the physician looks on distressingly limited in his power to prevent a subsequent and possibly fatal recurrence.

Probably because of difficulty in diagnosis and an insufficient number of postmortem examinations, the vital statistics do not give a true picture of the number of people in the United States who die yearly of pulmonary embolism. Belt¹ reported that of 567 consecutive unselected postmortem examinations of adults pulmonary embolism was found to be responsible for death in 65 per cent. The ratio of medical to surgical cases in that series was forty to sixteen. Pulmonary embolism was determined to be responsible for death in 272 per cent of consecutive postmortem examinations.

tions in McCartney's² series of 14,419 cases, in 9,615 of which deaths were "medical" and in the remainder were postoperative, posttraumatic and post partum Collins³ reported that 2.07 per cent of deaths were found to be from pulmonary embolism in 10,940 unselected consecutive postmortem examinations performed at the Los Angeles County Hospital. By com-

Fig. 2—The heart in a fatal case of pulmonary embolism. The right ventricle and right auricle have been opened to show the marked dilatation of those chambers.

paring McCartney's and Collins' series of necropsies, it is found that 2.36 per cent of all the deaths were attributable to pulmonary embolism. Subject to whatever selectivity such series of cases represent, one can estimate that 33,748 people die from pulmonary embolism yearly in the United States.⁴ If such a percentage of deaths from pulmonary embolism is applicable to the general population and the ratio remains the same in succeeding years, it may be assumed that 3,068,000 people now living in this country will die eventually of pulmonary embolism.

ETIOLOGY

The multiplicity of hypotheses to explain the occurrence of pulmonary embolism is an indication, on the one hand, that the cause is not known and, on the other, that several causes acting in combination are a more likely explanation. Lacking a known cause, nevertheless, investigators are beginning to appreciate the importance of several factors.

In McCartney's postmortem studies, previously mentioned, pulmonary embolism accounted for 1.89 per cent of 9,615 medical deaths, for 3.32 per cent of 2,139 deaths following trauma, for 5.1 per cent of 2,381 deaths subsequent to operation, and for 5.28 per cent of 284 deaths after parturition. Henderson⁵ found that pulmonary embolism accounted for 6 per cent of all deaths following operations at the Mayo Clinic from

1917 to 1927. Barker⁶ determined that pulmonary embolism was responsible for 5.8 per cent of deaths following surgical operation at the Mayo Clinic from 1928 to 1933. Females are more likely to die from pulmonary embolism than are males. Snell's studies indicated that obesity definitely predisposes an individual to fatal pulmonary embolism.

Age is a factor of conspicuous importance in pulmonary embolism, a fact stressed by many writers. Of Barker's patients on whom necropsy was performed 93 per cent of those who died from pulmonary embolism were more than 40 years of age, 70 per cent were more than 50 and only one was less than 30 years of age. McCartney has stressed the factor of age and has expressed the belief that certain operations are followed by a high incidence of pulmonary embolism as much because of the late average age of the patients when operation is performed as because of the type of operation. Thus, he found that herniotomy, which is performed usually after the patient has passed the age of 40 years, is followed by a much higher incidence of fatal pulmonary embolism than is appendectomy, which is performed when patients are much younger, on the average. Barker found that the rate of death from pulmonary embolism was five times as high following the performance of operations for inguinal or femoral hernia as it was after operations for chronic and acute appendicitis, excluding patients with rupture of the appendix.

The type of operation has an important bearing on the incidence of fatal pulmonary embolism. As everyone knows, most instances of fatal pulmonary embolism following surgical procedures are associated with abdominal operations. In Barker's series, resection of the stomach, exploratory laparotomy for inoperable malignancy, colostomy, enterostomy, repair of femoral or

Fig. 3—*a* early stage of pulmonary embolism involving the left lower lobe increased hilus shadow on the left due to dilated vessels; dullness at left base four days later increased dullness at left base due to infarction and secondary pleural effusion; persistence of increased hilus shadow. Necropsy showed an embolus in the left pulmonary artery with infarction of the left lower lobe and left pleural effusion.

inguinal hernia, resection of the intestine, hysterectomy, operations for ruptured appendix, operations on the prostate gland and bladder, open reduction of fractures, operations on the brain and spinal cord and cholecystectomy were accompanied by the greatest death rate from pulmonary embolism, in the order named. On the other hand, death from pulmonary

embolism following thyroidectomy is almost never encountered, in spite of many instances of severe cardiac damage found in examination of the patients. Of Barker's patients who died of pulmonary embolism, 42 per cent had some form of malignancy, this percentage is out of all proportion to the number of patients with malignancy of the total number who underwent operation.

Cardiac disease is an outstanding predisposing factor to pulmonary embolism. Thus, Belt found that of eighty-three patients who had congestive heart failure thirty-six had venous thrombosis and twenty-five had pulmonary embolism, to fifteen of the twenty-five, the embolism was fatal. McCartney found that fatal pulmonary embolism was practically twice as common among patients who had heart disease as it was among patients whose hearts were not damaged. He observed, further, that the presence of heart disease tended to displace the deaths from pulmonary embolism into the earlier decades of life.

For a long time it has been believed that a crucial defect in the circulation, relating to formation of thrombi and resultant pulmonary embolism consists of a reduced rate of venous blood flow, particularly in the legs. Normal venous circulation is maintained by the *vis a tergo* of the systemic arterial circulation, which depends on the maintenance of adequate systemic blood pressure, by contraction of the skeletal muscles, which presupposes activity of the muscles, by negative intrathoracic pressure, which results from normal respiration, and by the plunger-like action of the liver secondary to respiratory movements, tending to squeeze the blood out of the intra-abdominal venous channels. All these mechanisms are likely to be disturbed following operations on the abdomen. The blood pressure is prone to fall after operation, especially if the heart is damaged, movements of the legs are reduced and respiration is likely to be shallow and in consequence the excursions of the liver are diminished. Blumgart and Weiss⁸ have shown that in cardiac insufficiency the circulation time is prolonged, that the velocity of the venous return is reduced and that the veins of the lower extremities are the first to suffer when the circulation lags. Smith and Allen⁹ found that the velocity of the venous return is reduced in 40 per cent of cases following surgical operation. A rise in the platelet count following operation, coincident with the period of anticipated embolism, has been demonstrated¹⁰ but this occurs in young and old alike. Cohnheim¹¹ and Ribbert¹² pointed out that injury to the lining of a

blood vessel favors, if it is not essential to, the localization and development of a thrombus. Dawbarn and his associates have considered that the factors of stasis and high platelet counts, acting in combination, may lead to thrombosis. Correction of the circulatory defect would seem to be the easiest way in which to break this chain of circumstances.

The situation of the thrombi which give rise to pulmonary embolism is well established. Henderson found the commonest sites, in order of frequency, to be the iliac vein, the femoral vein, the pelvic veins, the prostatic venous plexus, the vena cava and the right auricle.

Although pulmonary embolism is seen in cases of thrombophlebitis, there is little evidence that the pulmonary embolism arises from the thrombus of the thrombophlebitis. Of 116 cases of fatal pulmonary embolism, Barker found that clinical evidence of femoral or iliac thrombophlebitis was present in only five. In each of these five cases the thrombus was intact to the level of the bifurcation of the vena cava but the remains of a fresh thrombus were found in the iliac veins of the opposite leg, indicating that the embolism was the result of a fresh thrombus. Belt's examination of the spontaneous and adherent thrombus revealed no significant inflammatory reaction in the wall of the vein. Barker studied the histology of fatal pulmonary emboli from the pulmonary artery in thirty cases and found evidence of organization in only two, in these it was slight and was confined to a very small part of the margin.

Even a brief experience teaches that the fatal pulmonary embolism is commonly preceded by one or more milder attacks. There was a definite clinical history of nonfatal attacks in more than a third of Barker's cases. Belt's observations led him to conclude that, as a rule, pulmonary embolism is not a single, but a recurrent, event with repeated migration of a blood clot over a period of hours or days leading up to a fatal termination (fig. 1). Recognition of these milder attacks is sometimes difficult, but it is of the utmost importance if the patient is to be given every safeguard in an attempt to prevent subsequent fatal pulmonary embolism.

DIAGNOSIS

One is accustomed to think that the cardinal signs of pulmonary embolism are cyanosis and dyspnea. It is necessary to avoid obsession with this conception and to regard, as a common picture of acute pulmonary embolism, shock, with or without dyspnea, with faintness, pallor, sweating, acceleration of the pulse, a marked fall in blood pressure, vomiting and sometimes collapse. If such seizures are more commonly interpreted as signs of pulmonary embolism, nonfatal attacks will be recognized and the clinical diagnoses of pulmonary embolism will approximate more closely the frequency with which these accidents are discovered at necropsy.

Not only may the classic symptoms of pulmonary embolism be lacking but the triad of diagnostic observations, that is, bloody sputum, pleural friction rub and signs of pulmonary consolidation, may not be present for twenty-four hours after the onset and in some cases they never are present. Belt has indicated that pulmonary infarction sometimes may be absent in cases of pulmonary embolism unless there is obstruction to the return venous flow from the lung, such as may be

caused by some structural or functional defect of the mitral valve. In support of this view he cited the work of Karsner and Ash,¹³ who concluded from their experiments that true hemorrhagic infarction with necrosis is produced by blockage of the pulmonary artery by a bland thrombus only if some obstruction to the return venous flow is introduced. This may explain the lack of diagnostic pulmonary evidence in some cases of pulmonary embolism.

In case the embolism is massive but still is sublethal, White¹⁴ has called attention to cardiac phenomena which are attributable to acute dilatation of the right ventricle and pulmonary conus (fig 2). Increased pulsation may be noted in the second and third interspaces to the left of the sternum. A loud systolic murmur in this region, and marked accentuation of the second pulmonic sound may be observed. In the same area friction rub may be heard. Gallop rhythm, best heard at the left of the sternum, is present occasionally. The veins of the neck may be dilated and pulsating. Cyanosis of extreme degree may be present in severe cases.

Electrocardiographic Differences in Acute Pulmonary Embolism and in One Type of Acute Cardiac Infarction

Type of Electrocardiogram Characteristic of Acute Pulmonary Embolism	T ₂ Type of Electrocardiogram, Characteristic of Acute Infarction of the Posterior Portion of the Left Ventricle
S ₁ constantly present and usually prominent	S ₁ absent or if present not exaggerated
S T ₂ —Take off usually below zero level	R T usually elevated rarely isoelectric and never depressed
T ₂ diphasic monophasic or upright rarely inverted	T usually inverted
R T ₂ occasionally slightly elevated	R T ₂ much elevated as a rule
T ₂ inverted may be cove plane	T ₂ usually inverted
Q ₂ frequently fairly prominent	Q ₂ frequently markedly prominent
Q ₂ pattern not present	Q ₂ pattern commonly present
Q ₄ usually within normal limits	Q ₄ usually within normal limits
T ₄ usually upright may be flat or diphasic	T ₄ usually inverted

Roentgenologic evidence of pulmonary embolism may be lacking in the early stages. Camp¹⁵ has called attention to accentuation of the hilus shadow on the side of the occlusion (fig 3). He has expressed the belief that this is attributable to dilatation of the pulmonary vessels on that side, and if so, it should be an early sign in the anteroposterior thoracic roentgenogram.

Acute pulmonary embolism and acute coronary thrombosis may have the following symptoms in common: sudden onset, pallor and sweating, precordial pain, weakness, vomiting and collapse, marked fall in blood pressure and acceleration of the pulse, leukocytosis, and elevation of temperature. Marked cyanosis and urgent dyspnea are encountered much more frequently in cases of acute pulmonary embolism than in cases of coronary thrombosis. Pain, on the other hand, is more severe and prolonged with acute coronary occlusion and usually is projected to the sternal region. The pain of pulmonary embolism usually is felt in the lateral regions of the thorax and may be made worse

by inspiration. A previous history of angina pectoris should influence one to think first of the possibility of coronary occlusion.

White, and McGinn and White¹⁶ pointed out that certain electrocardiographic changes were indicative of acute pulmonary embolism. I¹⁷ made similar observations independently, which corroborate White's results, and I have found these electrocardiographic changes of great importance in the diagnosis of pulmonary embolism and especially in its differentiation from acute coronary occlusion. In the accompanying table are recorded the characteristics of the electrocardiogram in pulmonary embolism and in recent acute infarction of the posterior basal portion of the left ventricle, with which pulmonary embolism is most likely to be confused.

Although the records of many patients who had pulmonary embolism, verified at necropsy, might be submitted, the two following cases, in which the diagnosis seemed well established on clinical grounds, illustrate important clinical and diagnostic features.

CASE 1—A man, aged 47, was admitted to the hospital Aug. 20, 1935, with a history of having had thrombophlebitis of the right leg in 1930 and recurrence of this condition six weeks prior to this admission. There were pain, redness and swelling of the right leg. The blood pressure was 130 mm. of mercury systolic and 80 mm. of mercury diastolic. The electrocardiogram was normal two days after admission. August 31 he felt as if he were going to faint on going to the bathroom and had to be helped back into bed. September 3 on attempting to use the bedpan, he became very faint, there was a sense of oppression in the chest, and he was nauseated, pale and sweating. The heart tones were distant, the pulse rate was 160 per minute and the blood pressure was 86 systolic and 62 diastolic. He was not cyanotic. The clinician in charge considered that he had had acute coronary thrombosis. The electrocardiogram, September 4, was not indicative of coronary thrombosis but strongly indicated that the accident had been one of pulmonary embolism. Roentgenograms of the thorax were negative September 5, 7 and 16. Except for a suggestion of bronchial breathing at the base of the left lung, and some increased transmission of whispered sounds over that area there were no diagnostic signs referable to the thorax. The patient had no further seizures and was discharged in good condition September 21.

Noteworthy features in this case were (1) a mild premonitory attack which was unrecognized, (2) marked symptoms of shock without cyanosis or appreciable thoracic pain, (3) paucity of manifestations on physical examination of the thorax, and (4) diagnostic electrocardiographic signs.

CASE 2—A woman, aged 48, underwent an operation for repair of a diaphragmatic hernia Sept. 18, 1935. September 20 she had a severe pain in the left anterior part of the thorax particularly worse on inspiration. The pulse rate was 104 per minute. The blood pressure fell from 120 systolic and 80 diastolic to 90 systolic and 62 diastolic. There was a suggestion of bronchial breathing at the base of the left lung on the following day. September 25 at 2:40 a. m. there was a sudden attack of dyspnea without appreciable cyanosis. October 4 the patient had pain in both shoulders, she became very weak and moderately dyspneic and she vomited. Her color was ashen but not markedly cyanotic. The apical rate was 136 beats per minute. The blood pressure fell from 110 systolic and 80 diastolic to 90 systolic and 62 diastolic. Repeated thoracic examinations never revealed evidence of pulmonary consolidation. T₁—

patient received oxygen continuously from September 18 to 27 and from October 4 to 16. After an alarming and stormy convalescence, she was dismissed November 5 in satisfactory condition. The electrocardiographic changes are shown in figure 4.

Noteworthy features in case 2 were (1) two mild premonitory attacks, (2) attacks characterized by a picture of shock rather than by marked dyspnea and cyanosis, (3) absence of diagnostic signs on repeated thoracic examinations, (4) importance of electrocardiographic appearances in the diagnosis, and (5) probable life preserving effect of oxygen therapy.

MECHANISM OF DEATH

A word must be said concerning the mechanism by which pulmonary embolism causes death. There are many objections to explaining it on the basis of arterial obliteration and insufficiency of the pulmonary circulation. These are that in some cases there has been time to remove the clot from the pulmonary artery by the Trendelenburg operation, that in pulmonary surgery it is possible to ligate one or all the branches of the pulmonary artery on one side, and that correlation between the size of the embolus and its fatal issue is lacking. Villaret, Justin-Besançon and Bardin¹⁸ produced pulmonary embolism experimentally. They found that section of the vagus nerves of the rabbit increased by sevenfold the quantity of embolic particles necessary to produce sudden death. Conversely, section of the cervical sympathetic trunks diminished by fourfold the quantity of embolic particles that was required to produce sudden death. Administration of atropine sulfate and ephedrine hydrochloride in conjunction delayed the occurrence of sudden death perceptibly. If, in addition, the animal was alkalinized by administration of sodium bicarbonate, it survived an otherwise fatal dose of embolic particles from an hour to several days. The injection of hydrochloric acid rendered the animal more susceptible to sudden death from a given amount of embolic particles. The investigators concluded that sudden death could be the result only of a reflex sympathetic inhibition and that such humoral factors as alkalinity or acidity may play an important role. This hypothesis of sympathetic inhibition appears to receive some support from, and at the same time accounts for, the clinical phenomena of shock seen so frequently in attacks of pulmonary embolism.

Gosset, Bertrand and Patel¹⁹ submitted evidence that the embolus is fixed in the pulmonary vessel by its spasm. There is evidence that in embolic occlusion of an artery elsewhere in the body the complete occlusion is often the result of arterial spasm²⁰ rather than of the actual size of the thrombus. Is it not possible, if sympathetic reflexes are important in the production of the total chain of serious events, that reflex spasm of some or all of the pulmonary arteries at the hilus may be at least one part of the dangerous reflex mechanism? The rapid dilatation of the right ventricle would be better explained on such a basis than on the basis of occlusion of a single pulmonary vessel.

PREVENTION AND TREATMENT

In selecting a plan of preventive treatment it is necessary to choose a point of attack which, with present knowledge, seems to give the most prospect of yielding results. According to the evidence at hand, the most logical program would seem to have for its aim improvement in the rate of circulation and particularly acceleration of the return flow of blood from the lower extremities. Smith and Allen have found that in a considerable proportion of their cases there was a reduction in the velocity of venous return flow from the lower extremities after operation. They have found also that desiccated thyroid, administered orally, increased the velocity of this venous return in from forty-eight to seventy-two hours after administration was begun. Walters²¹ in 1930 reported four and a half years of experience with thyroid extract administered to 4,500 patients after operation. Based on the total number of operations performed, the incidence of fatal pulmonary embolism in Walters' cases was 0.09 per cent as compared to an incidence of 0.34 per

Fig 4—Electrocardiograms in case 2. A obtained October 5. B obtained in the same case one year later. C obtained in a case of acute myocardial infarction of the posterior basal portion of the left ventricle.

cent in Henderson's series in which thyroid was not employed. It is difficult to arrive at a true estimate of the value of thyroid extract as a preventive measure. However, pulmonary embolism does occur in spite of medication with thyroid, hence it is desirable to use additional measures in an attempt to combat the hazard.

For a number of years we had a certain number of deaths in the cardiac service from pulmonary embolism. From 1926 onward, Willius employed, twice daily, centripetal massage of the legs of patients hospitalized for cardiac disease. Since that measure has been in use, we have not had a single death in the cardiac service from massive pulmonary embolism.

In one surgical service²² at the Mayo Clinic during the past year the following postoperative program has been followed in every case. The patient is placed in the Trendelenburg position for the first twenty-four hours after operation. Carbon dioxide is administered

by inhalation several times in the day and night for the first forty-eight hours. Frequent deep breathing exercises are urged in every case. Attempts at early coughing are encouraged as much as possible. Extreme care is observed to keep the patient's legs warm at the operation, during his transfer to his room, and after his return to bed. Frequent massage of the legs is practiced during the first forty-eight hours and twice daily thereafter until the patient is out of bed. Passive and active movements of the extremities are insisted on at stated intervals from the time the patient is returned to his room and until he is out of bed. For purposes of control, thyroid extract has not been administered to these patients, although there is no reason why its administration should not be combined with this regimen. On this program no patient has died of pulmonary embolus following 750 consecutive operations, most of which were laparotomies, and while the series is too small from which to draw conclusions, the procedure will be continued and form the basis of a subsequent report.

It may be objected that such a program is too burdensome. It is quite possible that some of the details may be omitted. But if a surgeon should find that in 6 per cent of the cases in which his patients died the fault was some error in aseptic technic, would he regard any routine too burdensome to overcome it?

As a matter of fact, for all practical purposes it is possible to restrict the procedure to a selected group of cases. First of all, its use could be largely confined to patients more than 40 years of age unless the patient, whatever his age, was obese or was suspected of having some circulatory defect. Efforts should be concentrated on patients subjected to an abdominal operation, and particularly to the operative procedures shown earlier in this paper to be followed by a high incidence of fatal pulmonary embolism. Patients with a malignant growth in the abdomen who require resection of a portion of a viscus especially belong in this group. Patients who are operated on for chronic or subacute appendicitis without rupture of the appendix, those on whom thyroidectomy is performed and those whose operations are on the superficial structures of the face and neck could be omitted from the list with almost complete safety. But once a patient is found to belong in a category in which there is large likelihood of pulmonary embolism, the program should be carried out with as much care and system as are the details of the surgical procedure.

Those patients who have given a warning in the form of a mild, premonitory attack indicative of pulmonary embolism offer to the physician the possibility of his taking certain precautions and making certain preparations to prevent or combat a more serious attack. Obviously, greater care must be exercised in the time and manner of the patients' subsequent efforts at getting out of bed. A syringe containing one-half grain (0.032 Gm.) of papaverine hydrochloride for intravenous administration should be in the patient's room or ready for immediate access at some convenient point. If a Trendelenburg operation is to be considered, a sterilized surgical set should be conveniently at hand. Arrangements should be completed so that an oxygen tent could be available at a few moments' notice. In this manner, maximal preparation for a severe attack could be provided.

In case of an attack, papaverine or other antispasmodic substances should be given at once, and enough

morphine to allay pain and combat the patient's anxiety should be administered. The patient should be placed in the semiupright position and should be allowed to breathe air with a suitable concentration of oxygen. If marked distention of the veins occurs and cyanosis is marked, venesection may be indicated. If the patient survives the attack, but with evidence of cardiac embarrassment, digitalis should be administered in suitable amounts. And finally, if the situation is desperate and the surgeon is at hand, the Trendelenburg operation should be considered.

SUMMARY

Death from pulmonary embolism is a much greater menace in both medical and surgical cases than is generally realized. Although its cause is not known, some of the factors that predispose to its occurrence are known. Mild premonitory attacks frequently precede the fatal seizure and it is important that they be recognized. The picture of shock, noted as much as or more commonly than marked dyspnea and cyanosis, may constitute the clinical symptoms of pulmonary embolism. The electrocardiogram may furnish invaluable aid in the diagnosis of this condition and especially in its differential diagnosis from acute coronary thrombosis. Whatever the cause of pulmonary embolism, the most promising avenue of attack is the attempt to improve the rate of circulation and particularly the velocity of venous return from the lower extremities. A comprehensive program looking to that end should be applied, if not to all patients, then to those patients whose condition presents circumstances which are known to predispose to the occurrence of pulmonary embolism. Certain results to date encourage one to believe that if such a program were carried out with uncompromising zeal a very high percentage of deaths from pulmonary embolism could be eliminated, at least following surgical procedures, during the puerperium, and following sprains and fractures. In no aspect of surgery is there such a promising field for lowering surgical mortality. The medical profession is challenged to use at least such measures as are available in the effort to combat the tragic situation presented by pulmonary embolism.

ABSTRACT OF DISCUSSION

DR. WILLIAM J. KERR, San Francisco. One of the points emphasized is the evidence on which one may be able to make earlier and more accurate diagnoses of this condition. A few years ago it was customary to make the diagnosis only when the patient had evidence of consolidation or collapse in the lung with a friction sound and with the expectoration of thick gelatinous, hemorrhagic material. It is not necessary to wait until those signs appear before the diagnosis can be established. The incidence of this condition is high in persons past 40 years of age, particularly in the group who have some circulatory impairment, in those who are subjected to certain types of operation which require rest in bed and some shock or symptoms result from the operation itself, in those whose abdomen has been opened, or in those having operations for hernia. Just how much the disturbance in the intra-abdominal pressure has to do with this cannot be said, but as Dr. Barnes has pointed out the movements of the diaphragm are essential in promoting the normal circulation. One of the facts that have not been fully appreciated until recently is that many of these emboli which plug the pulmonary vessels are not broken off from the older process in the iliac vessels or in the femoral veins but seem to be entirely fresh embolic masses as if they were formed somewhere between the original focus and their point of lodgment, or they may perhaps have formed in the pulmonary vessels themselves. Many times the origin of the

more recent thrombus is obscure, but the premonitory signs of thrombosis in the femoral or iliac vein should put one on guard for this complication. The slowing of the blood stream by a number of means, Dr Barnes has emphasized, calls for some of the procedures which tend to promote the circulation in the abdomen and the lower extremities. The symptoms of shock which Dr Barnes mentioned, accompanied so often by cyanosis and dyspnea, are the important symptoms on which the diagnosis can be established with such accessory aids as the electrocardiogram and x-rays. Years ago Dr Paul D. White emphasized the symptoms and signs of so-called cor pulmonale, in which there was sudden distention of the right heart such as is seen in these patients. Dr Barnes mentioned in his paper, but had not time to discuss it here, one of the great problems that arise in acute plugging of one of the vessels in the pulmonary circuit. Is the whole pulmonary vascular tree constricted through reflex disturbances and does this at that time give rise to the symptoms of shock? The plan that Dr Barnes has outlined is admirable, and the treatment of the relief of symptoms of shock is one that physicians should be prepared to introduce at any time under the circumstances mentioned.

DR O. H. PERRY PEPPER, Philadelphia. Dr Barnes has opened up a subject which is not adequately taught in medical schools or adequately covered in textbooks. I read the papers of the National Board of Medical Examiners two years ago, the graduates coming from practically every school in the country, and one of the questions concerned this subject. The question was poorly answered, and those who did answer it described only the severe fatal attack of pulmonary embolism. In the textbooks there is not only an inadequate discussion of this subject but some confusion as to terminology. Dr Barnes has discussed the similarity of coronary attack and embolism of the lung. There is one other condition, rare, I will admit, but giving an almost identical picture, and that is spontaneous pneumothorax. I should like to ask Dr Barnes when he thinks the thrombus forms. We know the date of operation, we know the late date at which the embolism usually occurs. When, during that week or ten days or more, does the thrombus develop which gives the embolic attack? Associated with that is a paradoxical situation, we are between the devil and the deep blue sea in treatment. I agree with Dr Barnes about the prevention of the original thrombosis which is what his measures of treatment are directed at. We improve venous flow, we avoid thrombosis in the femoral or iliac artery or elsewhere. This is all right. But now our patient has had a mild attack of pulmonary embolism. Right away we all more or less reverse ourselves. Instead of encouraging passive movements, getting the patient up out of bed, we establish a routine of immobilization and delayed getting out of bed, which while useful for preventing breaking off of the established thrombus is the exact program that would favor the establishment of further thrombosis. If the thrombus doesn't come from the femoral thrombosis that has been recognized, but from a fresh one, it seems to me that we are in a difficult position. While I think this is an important subject, I have a suspicion that pulmonary embolism is becoming less frequent, irrespective of the measures which Dr Barnes has suggested for avoiding it. The production of thrombosis is lessened by the better condition in which surgeons are bringing their patients through operation today. Better preoperative and better postoperative care, better anesthesia, better control of fluid intake and output exist, and the patients are less likely to develop thrombosis. In our clinic at the University Hospital in Philadelphia, where we take no special care such as that which has been described, we have had no case of pulmonary embolism for over two years.

DR DAVID WARD SCANLON, Atlantic City, N. J. Dr Barnes has estimated that of the people now living in the United States 3,068,000 will die of pulmonary embolism. That figure indicates the importance of his demonstrated pulmonary embolism electrocardiographic tracings. The clinical chart in the absence of electrocardiographic studies is diagnostic. For example, in a surgical case pursuing a normal postoperative uncomplicated course an acute complication suddenly occurs. The pulse jumps to 140 or above and remains there for about forty-eight hours. The temperature is not much affected by the complication until, at about the end of forty-eight hours it

climbs to between 100.5 and 102 and the pulse drops to about 120. Temperature and pulse run along at this level for several days. I approve the prophylactic treatment against pulmonary embolism described by Dr Barnes, in spite of the large amount of additional work. I am quite sure that many of us here who have no hospital connection, and others like myself, who have only a three months service, would surprise men like Dr Barnes and Dr Pepper, who seldom leave the institution, with the things we do in private homes, with such treatment as Dr Barnes described in pulmonary embolism, and often as the only help the intelligence of the family properly instructed. I appreciated Dr Barnes's paper. I learned a great deal from my study of the paper before the discussion, and I am quite sure that if I hadn't studied it before this discussion I would be as dumb about this subject as the students Dr Pepper has handled.

DR A. R. BARNES, Rochester, Minn. I am grateful for the discriminating discussion that this paper has received. To Dr Pepper's question as to the time at which the thrombus is formed, the answer is that we do not know. Pathologists tell us that the lack of organization of an embolus indicates that it is of relatively recent development, perhaps twenty-four to forty-eight hours at the outside. Dr Pepper called attention to the advice to observe greater precautions with a patient who has given a warning in the form of a premonitory attack. I admit that the advice sounds somewhat paradoxical. It reminds me of O. Henry's story "Let Me Feel Your Pulse." O. Henry represented that he had symptoms of a nervous breakdown. He went to one of the great sanatoriums for the treatment of nervous diseases. After an elaborate neurologic examination the doctor said "What you need is absolute rest and exercise." I did not elaborate on what I meant by certain precautions which might follow a premonitory attack. By no means would I have us give up, for example, deep breathing exercises, massage of the legs, or active and passive leg motions following that event, but I would postpone the time at which the patient is allowed bathroom privileges or allowed to be up. I would use unusual care to see that the bowel movements were made as easy as possible for the patient, perhaps by giving liquid petrolatum or small enemas, because all of us are familiar with the frequency with which fatal embolism comes after straining at the stool. I think it is possible to modify the strenuousness of the effort that is made but still to maintain a certain degree of effort activity, particularly pertaining to the activities of the legs and respiratory movements. Dr Pepper has made an optimistic statement and, I hope, one based on accurate data, that pulmonary embolism in the surgical services where he works has been on the decrease in recent years. It is extremely difficult to get at the actual facts in these cases unless the situation is analyzed with extreme care. Henderson analyzed our material for a period of ten years from 1917 to 1927 inclusive, and he found that 6 per cent of all surgical deaths were the result of pulmonary embolism. This report is based on necropsy studies. Since then we have instituted one program or another and we had the impression that we were making some progress. Barker has analyzed our necropsy material for the last six years and finds that pulmonary embolism accounts for 5.8 per cent of our surgical deaths despite our efforts at prevention. In other words, there is a screw loose some place in the efforts we have made heretofore. Hence our interest in tightening up on the situation and seeing if some more systematic method will not achieve the results we desire.

Billings, Osler, Welch and Garrison.—They all profoundly affected American medicine, particularly the study of medical history. It was Garrison's task in life to take a narrower path and climb it higher than any of the others—the rocky path of the history of medicine. He traveled fast and strong explored new ground and gained new vistas. He wrote an account of his travels his "Introduction," as all good travelers do for the benefit of those who should come after him. This book led more people to explore the same mountains than any other publication before its time.—Viets, H. R. Fielding H. Garrison and His Influence on American Medicine, *Bull. Inst. Hist. Med.* 5:352 (April) 1937.

TREATMENT OF TOBACCO AMBLYOPIA
WITH VASODILATORS

WALTER F. DUGGAN, M.D.

NEW YORK

In a recent article,¹ evidence was outlined for the hypothesis that tobacco amblyopia is due to a vascular spasm in the visual pathway. This etiology was suggested by A. Matland Ramsay prior to 1896 and later by Parsons, Aubaret and Sedan, Scalinci, Farnarier and others.

In 1930 Pfimlin² reported fifteen cases in which toxic amblyopia was treated with intravenous injections of sodium nitrite twice weekly for from three to eleven weeks. Eleven patients (73.3 per cent) attained vision of 6/12 or better in one or both eyes in an average time of thirty-six days, and seven patients (46.6 per cent) attained vision of 6/6 in one or both eyes in approximately the same average time. This was the first report to appear in the literature of the systematic use of vasodilators in the treatment of this disease. It was Pfimlin's impression that with abstinence alone a year would have been required to obtain similar results. Laszlo, Cordes and Harrington and I verified his results during the next four years. Cordes and Harrington³ used subcutaneous injections of sodium nitrite daily or every other day in treating six patients with toxic amblyopia without optic atrophy and with less than 20/20 vision. Five patients (83.3 per cent) attained vision of 20/30 or better in both eyes in an average time of twenty-four days, and three patients (50 per cent) attained vision of 20/20 in both eyes in an average time of ten days.

Finally, in 1935, I⁴ reported twenty-four cases of tobacco amblyopia without optic atrophy. Most of the patients received from six to ten intravenous injections of sodium nitrite (100 mg.), which were given daily when possible. Two patients were not improved, and one did not return for adequate follow-up. The remaining twenty-one (87.5 per cent) attained vision of 20/30 or better in one or both eyes in an average time of eighteen and four-tenths days, and twelve (50 per cent) attained vision of 20/20 in one or both eyes in an average time of thirty days.⁴ Five of these patients smoked during part or all of their period of treatment. The average time in which they attained vision of 20/30 or better was thirty-six days. For the sixteen patients that abstained from tobacco during treatment, the average time for the same improvement was twelve days, and ten of the patients attained this result within seven days. In addition, it was shown that daily injections were more effective than those given less frequently and that patients who had used both alcohol and tobacco improved more rapidly than those who had used only tobacco, as was demonstrated earlier by Usher.⁵

From the Herman Knapp Memorial Eye Hospital.
Read before the Section on Ophthalmology at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 11, 1937.

³ Cordes, J. C. and Harrington, D. O. Toxic Amblyopia Due to Tobacco and Alcohol Treated with Vasodilators. Report of Eight Cases. *Arch. Ophthalmol.* 13: 435 (March) 1935.

⁴ One patient was not seen between the seventy-sixth and the 120th day. Vision was 20/25 and 20/20—on the 120th day. If this patient who took an abnormally long time to improve is omitted (since the longest time for any other patient attaining a vision of 20/20 in at least one eye was fifty-two days) the average time for eleven patients who attained a vision of 20/20 in at least one eye is twenty-one days.

⁵ Usher, C. H. and Elderton, E. W. *Ann. Eugenics* 2: 245 (Oct.) 1927.

It is difficult to find reports on series of patients treated by abstinence either alone or in conjunction with strychnine, potassium iodide or sweats to serve as a control. According to statements of Griffith, Finlay, Traquair, Fuchs, de Schweinitz and others, mild or moderate cases require at least two or three months for a cure, while severe cases may require from five to thirty months.⁶ In 1935 Carroll⁶ reported seventy-two cases in which abstinence was the essential factor in treatment. He considered a patient improved if he could read at least two more lines on the Snellen chart than were read at the first examination. Of his seventy-two patients, seven showed improvement in two months, six in four months, five in six months, seven in nine months, four in twelve months and ten in over twelve months (the average was twenty months). This gives an average time of improvement of approximately nine months in 54 per cent of the seventy-two cases. A few patients improved who did not abstain, but in general improvement seemed to be directly correlated with partial or complete abstinence.

It has been assumed that sodium nitrite administered intravenously is effective in the treatment of tobacco amblyopia because of its vasodilating action. In order to verify this assumption, I deemed it advisable to use another vasodilator in a control series of cases. For this reason I began using acetylcholine chloride in the treatment of this condition in October 1933. The chemistry and physiology of acetylcholine were briefly outlined in a recent article,⁷ so they will not be described at this time. However, it may be stated that (1) acetylcholine is the most powerful vasodilator known, (2) it is rapidly destroyed or inactivated by blood and tissues and (3) it occurs normally in the body, being liberated on stimulation of parasympathetic (cholinergic) nerves. This last fact makes it valuable for establishing a comparison with patients treated with sodium nitrite because, instead of the introduction of a foreign substance (sodium nitrite) into the body, a substance normally present in the body in minute amounts is used. If the results obtained with acetylcholine even approximately paralleled those obtained with sodium nitrite, one could reasonably conclude that vasodilatation, a condition produced by both drugs, was the factor responsible for visual improvement in both groups of cases.

A few patients treated with sodium nitrite were not improved. It is probable that in these patients thrombosis of the vessel or vessels concerned had occurred (rather than a spasm). Likewise, patients with definite optic atrophy could not be expected to show much improvement in the condition. With such patients, however, the duration of the atrophy and the size, location and density of the scotoma are important factors for prognosis.

The salient features of tobacco amblyopia have been fully discussed elsewhere.⁸ In my opinion, the most important diagnostic procedure is a carefully taken field on the tangent screen at a distance of 1 meter with small (1 and 2 or 5 mm.) white test objects to determine the characteristics of the scotoma (size, shape, slope and density). The defect for red, which is disproportionately large, is valuable chiefly in the differential diagnosis.

RESULTS OBTAINED BY OTHER WORKERS WITH
ACETYLCHOLINE

In 1931 Bonnefon⁹ reported definite and rapid visual improvement in thirteen cases of toxic amblyopia following intramuscular injections of acetylcholine. He gave no details concerning the original or final vision in his cases nor did he state the time required for improvement.

In May 1936 Villard¹⁰ informed me that two patients with toxic amblyopia had been cured in approximately three weeks with injections of acetylcholine.

In July 1936 Orr¹¹ reported four cases of tobacco amblyopia in which the patient was improved with

Orr noted that complete abstinence from tobacco was lacking in some of his cases. He also asked for a further trial of the drug by other workers.

Late in 1936 Cragg¹² reported encouraging results in five patients following acetylcholine therapy. Two of his patients also received 4 mg of physostigmine sulfate daily by mouth.

ANALYSIS OF TWENTY-TWO CASES OF TOBACCO
AMBLYOPIA WITHOUT OPTIC ATROPHY
IN PATIENTS TREATED WITH
ACETYLCHOLINE

Between October 1933 and July 1936, twenty-two patients with tobacco amblyopia without optic atrophy

TABLE 1—Data on Patients with Tobacco Amblyopia Without Optic Atrophy Treated with Acetylcholine

Case	Age Years	Duration of Loss of Sight	Tobacco Used		Alcohol Degree of Use Duration of Use	Vision Before Treatment	Fundus	Intramuscular Injections of Acetylcholine	After Treatment Began

21	44	3¾ mo	4½	20	Heavy 8 yr	R 20/70 L 20/70	Temporal pallor	13 in 33 days	R 20/25 L 20/30	29	9	1½ mo
22	70	3 mo	3½	40	Slight 10 yr	R 20/50 L 20/-0	Arteries small	6 in 6 days	R 20/40 L 20/30	6	6	6 mo

In cases 1, 2, 9, 16, 17, 20 and 21 only cigarettes were smoked.

In cases 4, 9, 12, 16 and 22 the patient did not abstain from tobacco during part or all of treatment.

acetylcholine. His results may be summarized briefly as follows:

Case 1. Vision improved from 1/60 to 6/9 in forty-four days with forty-four injections.

Case 2. Vision improved from 1/60 to 6/12 and 6/6 in thirty-five days with fourteen injections.

Case 3. Vision improved from 4/60 to 6/12 in eight days with thirty-one injections.

Case 4. Vision improved from 6/12 to 6/6 in seven days with six injections.

were treated with intramuscular injections of acetylcholine chloride¹³ at the Herman Knapp Memorial Eye Hospital (table 1). In addition, two patients with optic atrophy were treated. The vision of the first improved from 20/200 and 11/200 to 20/70 and 20/200 after four daily injections but showed no further change during the following month. The second

13. Acetylcholine is available as the chloride in ampules of 100 mg both in solution and as a powder which is to be dissolved in 2 cc of sterile water just prior to injection. All injections were made into the deltoid muscle. No unpleasant or dangerous side actions were observed. Occasionally the patient observed that the arm on the side of the injection felt heavy and numb for a few minutes after the injection.

received six daily injections, the vision of the left eye improved from 11/200 to 20/200, which was maintained for one month, but the vision of the right eye (20/200) was not improved.

As complete a history as possible was obtained from all patients. The consumption of tobacco was based on the amount purchased by the patient. From a few determinations it was estimated that a cigaret weighs 1 Gm, a pipeful 1.3 Gm, an ordinary cigar 7 Gm, an Italian cigar 3 Gm and a package of tobacco 50 Gm. These figures are only approximately correct. With reference to the alcohol used, the patients were classified as those using none, as slight drinkers, who took an occasional drink of beer or whisky, as moderate drinkers, who took two or three glasses of whisky or a bottle of wine daily, or as heavy drinkers, who drank at least a half-pint of whisky or gin or two bottles of wine a day.

The visions reported are with correction in all cases. Retinoscopy was done before treatment was instituted in most of the cases to determine the approximate refractive error. The importance of this step was demonstrated in the case of one person who was

noon, three appeared, one sent word that his vision was normal and nothing was heard from the rest.

The patients received as an average seven injections in nine and one-half days. Sixteen patients received daily injections, the other six received injections on every other or on every third day. A patient was not considered to be improved unless any improvement attained was maintained until later visits.

Six patients were Americans, five Irish, four Negroes, three Italians, two French, one Hungarian and one Jewish. One was a woman (case 20).

The average age of the twenty-two patients was 51.7 years, and seventeen (77.3 per cent) were between 41 and 60.

The average amount of tobacco used per week was 5½ ounces (165 Gm), and the average duration of use prior to the onset of amblyopia was nearly twenty-six years. The least total amount of tobacco used was 4½ ounces (128 Gm) per week for one year, the greatest, 14 ounces (397 Gm) per week for thirty-five years. The least amount used per week was 1 ounce (28.35 Gm), the greatest, 16 ounces (454 Gm). The shortest period of use was one year, the longest, fifty-eight years. In seven cases (1, 2, 9, 16, 17, 20 and 21) only cigarets were smoked.

The average duration of loss of sight prior to treatment (for twenty-one cases) was four and one-half months, the extremes being one month and one year.

In table 1 are included all the essential data for the twenty-two patients treated with acetylcholine. The visual results are summarized also in section A of tables 2 and 3. There is no correlation between the amount of tobacco used (or the duration of use) and the extent of visual loss, the rapidity or slowness of improvement or the appearance of the fundi. This had been noted previously by Usher,⁶ Carroll⁶ and Duggan.¹

In two cases (1 and 21) a dermatitis of the hands was present which was diagnosed as alcoholic pseudopellagra.

CASE 1—A man, aged 54, had used 4½ ounces (132 Gm) of tobacco a week for thirty years. He had also consumed a quart of gin daily for six months and at least a pint daily for several years prior to that. His vision, which was 20/100 in the right eye and 6/200 in the left eye, had been failing for six weeks. Both disks showed temporal pallor. A scotoma, larger for the left eye than for the right, was easily found with a 5 mm white test object. The only positive results of a medical examination were a history of diarrhea and the discovery that the knee jerks were elicited only on reinforcement and that there was dermatitis on the back of both hands. The medical diagnosis was alcoholic pseudopellagra.

The vision in the right eye improved to 20/20 in five days with three injections of acetylcholine, the vision in the left eye improved to 20/200 in nine days. Two more injections did not improve the vision further.

CASE 21—A Negro, aged 44, had used 4½ ounces (132 Gm) of tobacco a week for twenty years, and he admitted drinking a half-pint of whisky daily for eight years. His vision had been failing for three and one-half months. He also mentioned the fact that his appetite was poor. The vision was 20/70 in each eye, there was temporal pallor of both disks and there was a paracentral scotoma in the field of both eyes. As he had a marked tremor of the hands and some unsteadiness in gait he was examined neurologically by Dr. S. C. Burchell who stated that the tremor and difficulty in walking were of alcoholic origin and that the patient had had delirium tremens. The patient also had a dermatitis of the hands which was diagnosed as pseudopellagra at Roosevelt Hospital.

He received nine injections of acetylcholine in twenty-nine days, with improvement of vision to 20/25 and 20/30 which was maintained for two weeks more, after which he failed to return to the clinic. It is of some interest that his tremor

TABLE 2—Vision Before and After Treatment of Patients Improved By Vasodilator Therapy

Vision	A Forty One Eyes Improved with Acetylcholine			B Forty Eyes Improved with Sodium Nitrite		
	Before Treatment Eyes	After Treatment Eyes	Average Time of Improvement per Eye	Before Treatment Eyes	After Treatment Eyes	Average Time of Improvement per Eye
<20/200	8	0		8	0	
20/200	2	2	7.5 days	8	0	
20/100	5	1	21.0 days	8	0	
20/70	12	5	10.2 days	8	0	
20/50	5	4	16.3 days	3	2	9.0 days
20/40	2	2	20.0 days	1	3	7.0 days
20/30	7	9	10.7 days	4	7	11.4 days
20/25	0	6	17.7 days	0	13	24.0 days
20/20	0	12	10.8 days	0	15	27.7 days

A Twenty-two patients were treated with acetylcholine. One was not improved.

B Twenty-four patients (46 eyes) were treated with sodium nitrite. Two were not improved and one did not return for follow up.

referred to me for treatment. The vision was 10/200 in each eye, and he was a heavy smoker. Retinoscopy revealed more than four diopters of hyperopia, with hyperopic astigmatism in each eye. With the proper glasses, vision was 20/20 in each eye, and the visual fields were normal for white and colors. If the patient had been treated with acetylcholine and refraction had then been performed, he could easily have been considered as a rapidly cured patient.

Visual fields were taken on the Thomasson tangent screen at a distance of 1 meter with 1, 2 and sometimes 5 mm white test objects and a 5 or 10 mm red test object. Ten foot-candles of illumination was used. As the scotomas were typical in all cases, the changes in the fields have not been included in this report. However, the importance of this diagnostic procedure was demonstrated in two patients who were referred to me as having tobacco amblyopia. Both had bitemporal hemianopic scotomas which were obviously due to tumors in the vicinity of the optic chiasm.

Neurologic and other examinations were made when indicated, and the patients were observed as long as possible. As mentioned before,¹ such patients are uncooperative and many of them stop attending the clinic as soon as they have recovered what they consider to be adequate vision. For example, fifteen of the patients were requested to return on a stated after-

and difficulty in walking disappeared during the first eight days of treatment (seven injections were given during this time) and did not recur while he was under observation

Carroll¹⁴ recently reported nine cases of alcohol amblyopia associated with pellagra or polyneuritis in which the patient was treated with a diet high in vitamin B. All his patients used some tobacco. Some were definitely improved in vision when placed on a diet rich in vitamin B. There are apparently two types of toxic amblyopia, one due to tobacco, with or without alcohol, and the other a deficiency disease in which the vitamin B intake is lowered because of the patient's lack of desire to eat, which, in turn, is due to an excessive intake of alcohol. Carroll has discussed the latter type and its treatment so recently that further discussion is unnecessary at this time. However, it is of some interest that in the two cases just described, which apparently were of the type of amblyopia he reported, the patient was definitely and rapidly improved with vasodilator therapy.

An apparent relation between spasm and thrombosis was demonstrated in the following case.

CASE 14—A man, aged 74, was seen first on July 26, 1934, because of retinal venous thrombosis in the left eye, the vision being reduced permanently to 10/200. The vision in the right

20/20 in each eye after the third daily injection, and this improvement was maintained for the five weeks the patient was under observation. His improvement was definitely more rapid with vasodilator therapy than it had been when abstinence was the only therapy used.

Patients 4, 9, 12, 16 and 22 did not abstain completely from tobacco during treatment, in spite of which most of them showed definite and fairly rapid improvement in vision. Also, in case 22 incipient cataract was present in both eyes, which prevented the attainment of 20/20 vision. These cataracts have slowly progressed during the past nine months, so that the vision is now 20/70. There is no scotoma for red or green in either eye.

COMPARISON OF RESULTS OBTAINED WITH ACETYLCHOLINE AND WITH SODIUM NITRITE IN CASES OF TOBACCO AMBLYOPIA WITHOUT OPTIC ATROPHY

1 *Results in Patients Treated*—Of the twenty-two patients who were treated with acetylcholine, one was not improved. Sixteen (72.7 per cent) attained a final vision of 20/30 or better in at least one eye in an average time of fourteen days, and seven (31.8 per cent) attained a vision of 20/20 in at least one eye in an average time of thirteen days.¹⁵

TABLE 3—Rapidly of Visual Improvement in Patients Treated With Vasodilator Therapy

Best Final Vision Attained In	A Forty One Eyes Improved with Acetylcholine						B Forty Eyes Improved with Sodium Nitrite						C Total (81 Eyes)				
	Final Vision						Eyes	Per centage	Final Vision						Eyes	Per centage	Eyes
1-3 days	20/20 (3)	20/30	20/50				5	12.2	20/20 (3), 20/25	20/30	20/50		6	15.0	11	13.6	
4-7 days	20/20 (3)	20/25	20/30 (2)	20/40	20/50	20/70 (3), 20/200	12	29.3	20/20 (2)	20/25	20/30 (3)	20/40 (2)	8	20.0	20	24.7

61-120 days									20/20	20/25			2	5.0	2	2.5	

eye was 20/30 at this time and during the following ten months. He was seen again on Oct 4, 1935, with the complaint of failing vision in the right eye for three months. The vision in this eye was 20/70, and there was a moderately large paracentral scotoma. The vision improved to 20/30 in seven days with seven injections of acetylcholine and this improvement was retained for more than six months. Then the vision failed rapidly to 20/200, and a large, dense cecocentral scotoma was found. Vasodilator therapy was completely ineffective this time, and optic atrophy developed.
